TUBERCULOSIS IN THE FRENCH ARMY DURING THE WAR.*

BY COLONEL C. U. DERCLE,
MEDICAL CORPS, FRENCH ARMY.

ON DUTY IN THE OFFICE OF THE SURGEON GENERAL, U. S. ARMY.
WASHINGTON, D. C.

MR. PRESIDENT AND MEMBERS OF THE AMERICAN SANATORIUM ASSOCIATION: I esteem it a great privilege and a real honor to be thus admitted to your Association. I thank you very much. I am glad of the opportunity to address you, because it seems to me that this, above all other times, is the time for common counsel, for the drawing, not only of the energies but of the minds of all together. I thought indeed that it was a welcome opportunity for disclosing to you some of the thoughts that have been gathering in my mind about the so important question of tuberculosis in the French army since the war.

I have often been interviewed as to the frequency of tuberculosis in the French army. The indirect manner in which the questions were asked excited my suspicions and led me to seek the reasons for such persistence. Following the thought of my interlocutors, I soon perceived that a legend had been created as to this malady, said to rage in France, making it a veritable bogey.

I have heard it said that the American people, so thoughtful and at the same time so courageous, have the terrifying conviction that the entire American Army is doomed to death upon the soil of France. And what is to be the agent to sweep it away? You will think perhaps that it is the engines for destruction of every kind employed by the Germans—rifle balls, artillery projectiles, bombs from aeroplanes or Zeppelins, asphyxiating gases? Not at all. Certainly it is admitted that a great number will inevitably be victims of these murderous engines, but it is declared also that those who will be spared by them will encounter another enemy, as implacable, since it also slays—I mean pulmonary tuberculosis, which they will not escape.

Without intending to diminish the gravity of the tuberculosis situation in my country, resulting from the prolonged war, I still cannot admit that it is as serious as certain ones claim. In this short address I wish to consider this point of view. I propose to go back to what I believe to be the origin of these exaggerated rumors. I shall show upon how slight a foundation they are based, and set before you the real truth, stripped of all concealment, just as it appears from official statistics received a few

days ago. Finally, I shall try to draw a conclusion.

As a matter of fact, in the beginning* of the war, our medical men considered it their duty to send back to the field hospitals all the drafted men whom they regarded as suspicious of tuberculosis. From the field hospitals they were sent to base hospitals in the interior, and a number of them were definitely discharged, a very considerable number indeed.

In December, 1915, at the French Academy of Medicine, Professor Landouzy, Dean of the Medical Faculty, published the official figures, which showed that during the first year of the war no less than 86,000 men had been discharged from the army on account of pulmonary tuberculosis.

They were really appalling figures and spread much alarm, not only in France but in allied and friendly countries, and especially in the United States, of course. From the beginning and long before you actually entered this war, the men and women of your country had given to France, in her distress, the most generous, the most lavish, the most uncompromising moral and material support. Long before you entered the war, young men from America fought and died on the battlefields of France for what is now our common cause. Long before you entered the war, doctors, nurses, social workers, and ambulance drivers from America came to take care of our wounded and sick, to give a home to our widows and orphans. From these states came warm clothing for our soldiers in the trenches, and Christmas presents for our refugee children. Millions of dollars have been given by individual Americans to alleviate the misery of fighting France.

No wonder, therefore, that this terribly high rate of discharge for pulmonary tuberculosis came as a shock to our American friends. No wonder that they had the impression that the whole French nation was literally permeated with tuberculosis and was sure to die from it, if immediate measures were not taken to prevent it.

But this high figure, 86,000 discharges for tuberculosis in one year, contrasts so strikingly with the experience of the tuberculosis experts, who were working in the French army, that it cannot be admitted as representing the real condition of things. What it represents is nothing but the sum total of diagnosis of tuberculosis made by average practitioners, accustomed to stamp as tuberculosis every throat or lung affection which was not manifestly something else.

Undoubtedly, it is extremely important not to

*Read by invitation before the American Sanatorium Association, at its 13th Mid-winter Meeting, at the New York Academy of Medicine, December 14, 1917.

*The following paragraphs are from an address delivered by Major Rist of the French Army, at Fort Benjamin Harrison, and published in the *Military Surgeon*, December, 1917.

admit into the ranks men who are in the early stage of active tuberculosis. But it is equally important not to reject, on account of a mistaken diagnosis of active tuberculosis, men who are really fit for military service. It would not only be improper, it would be unjust. Doubtless there is no one in our profession who is not aware of the great diffusion of endemic tuberculosis, of the danger which results from it, for the nation as well as for the individual, and of the necessity of struggling against the evil. Nor does anyone fail to admit the peculiar contagiousness of pulmonary phthisis, its curability when it is treated early, and, consequently, the especial interest which is attached to the early diagnosis of the affection and to the discovery of its masked forms. But the progress of modern medicine has given to tuberculosis so preponderant a rank in pathology and in nosology, it has set forth so strongly its frequency, the variety of its effects in the individual, and the gravity of its consequences for society; it has worked so anxiously against the stealthiness of its beginnings, and the infinity of its disguises, that, in the presence of this disease, *par excellence*, many physicians lose their balance. They are haunted by tuberculosis. So that when a patient coughs, loses weight, or presents abnormal temperature, the first question which occurs to them is not what is the matter, but rather, has he tuberculosis or not?

Among the numerous lesions of the lungs are those created by the tubercle bacillus; they are certainly the most frequent, but they are not the only ones, and one cannot depend upon their frequency to relieve himself from the obligation of justifying the diagnosis by certain proofs, especially by that given by the bacilli in the sputum. In too many cases one has acquired the habit of presuming the existence of tuberculosis a priori. The peril which this state of mind creates is great even in peace; it is not a matter of indifference to pronounce an individual tuberculous, when he is not. But in time of war the peril grows worse for the nation, for it means so many soldiers, really in good health, eliminated from the army.

This is what happened. The melting away of the effectives, under the pretext of tuberculosis, assumed such alarming proportions that it became the absolute duty of the physicians to resist this deplorable tendency.

Major Rist, of the French Army, well known to many of you, and whose activities as a physician in civilian life, as a hospital and laboratory worker, and as a teacher, are entirely devoted to the question of tuberculosis, was one of the first to do this.

This is what he says: "During the whole of 1915, and half of 1916, I was in charge of a large hospital in the war zone. This hospital was part of a group of hospitals of which I was the consultant physician. At first my activity was absorbed by the typhoid situation. But later on, when the typhoid outbreak subsided, I was able to give some attention to the question of tuberculosis in that particular section of the front. A very great number of men were sent from the advanced front to the hospital center with a diagnosis of tuberculosis. A large percentage of them did not exhibit any sign of tuberculosis on close examination, but the practice in this hospital center, which was often con-

gested and often shelled by the Germans, was to send to the base hospital in the interior all such cases. Our base hospitals at that time consisted of a great number of small units, scattered over the whole country, mostly under the care of civilian doctors, local practitioners, who were only too prone to regard as tuberculous all suspicious cases and to propose them for discharge.

"I very soon saw the necessity of holding in the field hospital all these cases and of sending to the base hospitals only the men who could be pronounced tuberculous on justifiable grounds. At my suggestion the medical officer in command of that section of the war zone ordered all the men coming from the front with a history of coughing, of blood spitting, of pleurisy, or with a diagnosis of tuberculosis, to be taken to a clearing station, of which I was given charge. All the men had their sputum examined in my laboratory; all were x-rayed by myself and all were examined by a throat and nose specialist. They were kept in my ward for an average of a week and were thoroughly examined.

"The result of this procedure was that in a few weeks I was able to send back to duty at the front several hundreds of soldiers who, if there had been no clearing station for such cases, would have been sent to the base hospital with a diagnosis of tuberculosis, would have been kept for months in the interior, and the greater part would have been finally discharged. As a matter of fact, between 80 and 90 per cent of those supposedly tuberculous soldiers were not tuberculous at all."

These observations are not the only ones that have been recorded. The clinical data from the clearing station have been corroborated by those of others, created since that time.

Here are indeed other facts, reported by the well-known French physician, Major Emile Sergeant, member of the Medical Society of Paris, and by Colonel Delamare, physician in chief of our military hospital in Paris, called Val de Grace. These physicians communicated to the Academy of Medicine of Paris, on October 31, 1916, the results of an examination of 600 soldiers, sent as tuberculous suspects to the clearing station. From their results it appears that the diagnosis of this affection should be admitted only after sufficient observation and after methodical use of the various diagnostic procedures which are employed at the present time. They established the fact that though the danger of the tuberculosis of war is incontestable, and though it is well to strive against it, yet it is not necessary, on the other hand, to fall into a tuberculophobia. Of the 600 soldiers of the service, 89 were recognized to be non-tuberculous, only 83 expectorated tubercle bacilli; the other 428 represented the most complex group—that of the suspects; that is to say, the patients who, though not having the tubercle bacillus in their sputum, yet presented clinical and radiological anomalies capable of invoking the idea of tuberculosis. Of these 428 suspects, a methodical examination permitted the recognition of 216 cases of tuberculosis in evolution, and 212 healed cases. If to these cicatrized cases one adds the 89 subjects recognized to be non-tuberculous, one obtains the imposing number of 301 soldiers free of active tuberculosis in this group of 600, that is, almost exactly 50 per cent. These results demonstrate

most strongly the importance of the service rendered by the clearing stations, which alone can safeguard the interests of the individual, of the fighting force, and of the government.

Indeed, such clearing stations, with a laboratory for sputum examination, with an x-ray department, and a nose and throat expert—the latter because the most frequent cause for chronic recurrent coughing outside of pulmonary tuberculosis is to be found in the nasal condition—such clearing stations, I say, were established in every French unit, called army.

Those experiences at the clearing stations, and the reports which were issued from them, were received at first with quite an amount of skepticism. But later on other tuberculosis experts in France, such as Besançon, came forward with facts which certainly corroborated the views of the others. Since that time the number of discharges on account of tuberculosis has been considerably reduced. I have received recently the figures concerning the first 1,000 cases examined in one of these newly created clearing stations; they are very interesting.

Out of the 1,000 men who had been sent to the clearing station with a diagnosis of tuberculosis, 193 only had active tuberculosis—less than 20 per cent. Here are indisputable facts—and facts are worth more than all the arguments.

To return now to Dr. Landouzy's 86,000, here are corrections very recently obtained from the Minister of War at Paris. Landouzy's figures (86,000) must be diminished by 11,000 men temporarily removed from the army who were wrongly considered to be positive cases of tuberculosis and who, recently re-examined, have been, in great part, reincorporated into the ranks; and (A) by the erroneous diagnosis 50 per cent. of the patients are separated in the clearing stations as exempt from all active tuberculosis—this is the average for all clearing stations—and (B) by 8 per cent. cases of false tuberculosis who, notwithstanding the clearing stations, reach the hospitals.

Finally, the monthly mean of those eliminated for tuberculosis from August, 1916, to July, 1917, is 530.

Here, at last, are the facts, which have all the authenticity that can be desired, the veracity of which can be absolutely relied upon.

There is no doubt that war, with its formidable appeals to physical and moral courage, its material privations, its intense emotions, its food sometimes insufficient or badly cooked, its cold, etc., predisposes to the awakening of ancient latent foci practically healed; or that it develops elsewhere new internal foci, under the influence of violent physical exertions, which stimulate the circulation of blood and of lymph and facilitate the dissemination of germs.

On the other hand, life in the open air, muscular exercise, and the strengthening of the character are adjuvants against the effect of infectious germs. Also, in many cases, the ancient foci remain latent and the number of men in whom tuberculosis manifests itself in an active state is less than might have been expected. This appears from the relatively low figures of 530 per month discharged for pulmonary tuberculosis, referred to above.

It should be added that, of these 530, there is a large number who have returned tuberculous from captivity. There is nothing strange in that for one

who knows the pitiable condition of our compatriots, prisoners in Germany. How much unmerited suffering, how much misery, has been undergone! One refuses to believe it.

The official reports of the Ambassador of the United States at Berlin were needed before the civilized world could begin to comprehend what was happening in the prison camps, the camps of reprisal, and the places of compulsory toil. It was unworthy of a civilized nation.

The picture made by an impartial observer, a neutral, a Danish physician, Dr. de Christmas, in his book entitled "The Treatment of the French Prisoners in Germany," gives the impression that Germany has been led to trample under foot the highest of the social virtues, that which is greatest in humanity, sublime pity. Through the thought of Dr. Christmas one sees the manifestations of the satanic efforts of an impious race, a cursed race, which strives for the destruction of another race, our race; of the English race, and, we may say now, of your race.

All the faults against hygiene, the homicidal overcrowding, the rottenness, the vermin, the cold, the hunger, and the punishments inflicted upon the sick and wounded—all this foulness is said to have been regulated, wished, distributed by order to the vanquished.

The murderous epidemics of typhus, of typhoid fever, of dysentery—in a word, all the pathology which decimates our unfortunate brothers, chained in the frightful camps of concentration or of reprisal—are said to have been kept up if not planned.

And, to say all in one word, pulmonary tuberculosis, the supreme evil, since it is the inevitable result of privation, of insufficient alimentation, of overcrowding in a vitiated air, of all prolonged physical or moral suffering, pulmonary tuberculosis is said to have been actually cultivated in the French prisoners by their executioners. And this, perhaps, for the sole purpose of sending them to us as "carriers of the germs of death," after peace has been signed.

It is a new war, says Professor Letulle, of the Academy of Medicine in Paris, which we cannot avoid more than the other. We must accept its terrible burdens, and we do accept them as our implacable enemies impose them upon us. Conscious as we are of all our duties, prepared for the formidable To-morrow which menaces us all, in our health, in our families, in our race, we have only to act quickly and to act well.

It is by thousands that our brothers in arms return to us, and it is by tens of thousands that they will return after the war—free, but wounded with tuberculosis, according to the expression of Landouzy, and, for the most part, infectious. We are endeavoring to ward off this disaster of the present and the future by creating in all the territory of France dispensaries, houses of treatment and repose, asylums in which we are receiving, and shall receive fittingly, those who have doubly suffered. We receive them as heroes and they merit it; we dry their tears, we save their families, and, especially, we seek to cure all those who are still curable.

France has made barbarism recoil; it has saved the world, it shall not die, conquered by the last but

the most formidable ally of Germany, our all-powerful hereditary enemy, the tubercle bacillus!

In conclusion, I think we are justified in considering that out of the 86,000 soldiers discharged during the first year of the war less than 50 per cent, and even, as you have heard less than, 20 per cent., were really tuberculous. The calculations which have been based on this figure of 86,000, and which tended to show that there was much more tuberculosis in France than in any other country of the world, must, therefore, be corrected to a considerable degree.

We may then confidently reassure the anxious mothers of this country, who have naturally been much concerned by the rumors which have been circulated about the prevalence of tuberculosis in the French army, and who have been told that their own sons would be exposed to the tuberculous contagion in France. They may be sure that in France there is constant attention paid to the sanitary service, in order to procure the best conditions of health for all the troops which are on her soil, to put them into the best shape to gain the final victory, which is certain, what may be.

TUBERCULOSIS AND WAR.

BY COLONEL G. E. BUSHNELL,
MEDICAL CORPS, U. S. ARMY.
WASHINGTON, D. C.

WE have just heard the moving reference to the tragedy which has overwhelmed our ally, France, from the lips of one who is himself a hero and a victim, who bears in his body almost countless scars, who has gone to the very gates of death from wounds incurred while succoring others, and has returned again to vigorous health. Let us hope that as this is true of the representative of France it will not be less true of his beloved country, that it also will again flourish in freedom and in vigor, unmutated, its lands now occupied by the enemy restored to it, its sufferings forgotten in prosperity and in undisturbed peace and security.

I was desirous that you should hear the facts as to tuberculosis in the French army, not only because the prevalence of the disease has been much exaggerated, but because the experience of France brings a lesson for us.

The examiner for tuberculosis in military practice has two dangers to avoid. The civil examiner has but one. The latter desires to avoid, above all things, failure to detect tuberculosis, whereas the military observer has to detect all tuberculosis on the one hand, and on the other must be equally careful to avoid the error of classing cases as active which are really those of arrested tuberculosis or are not tuberculosis at all. The first thing that an army must have is men. While it is necessary to remove the sick from it, is it not equally or more necessary that no steps shall be taken which shall interfere with the formation of the army by the needless exclusion of those who are able to bear arms? If you have visited one of the cantonments of the National Army you have seen a town of such extent that you despaired of encompassing it by your own powers of locomotion—a town everywhere

swarming with inhabitants. Yet none of the cantonments at present have more than 40,000 soldiers, and some have a much less number. Now, if we recall the fact that of the 86,000 soldiers of France declared to be tuberculous, in the figures of Landouzy, only 50 per cent. have been found to be really tuberculous, we shall see that by errors of diagnosis a number of men have been unnecessarily removed from the fighting force of France that equals the number of soldiers in one of our most populous camps. Not only have more than 40,000 men been subtracted from the none too large army, but these men have occupied space needed for the sick, have taken the time of the overworked surgeons, have needed for their feeding and maintenance in idleness the services of a numerous corps of attendants who might better have been employed elsewhere. These cases of erroneous diagnosis were, of course, scattered through the millions of the army, and thus escaped observation until the statistics had been formed. But supposing that they had all been collected together at one place, and at one time, and that some one, pointing out the vast assemblage, had said: "Here is an army of men not allowed to fight on account of the errors of the physicians, who say they have a deadly disease, when really there is nothing the matter with them." Fancy the indignation of the patriot at such an unheard-of spectacle! Now, gentlemen, it is an evil of this kind, less spectacularly exhibited, from which we have endeavored to protect our army. In examining for tuberculosis, we try, first of all, of course, to exclude cases of active tuberculosis, but we have given equal thought to the question how to protect men who were really fit to serve from being excluded, on the ground of the existence of some uncertain or slight indications of past mischief. As I have pointed out elsewhere, the evils of such faulty diagnosis are world wide; they have been encountered in the armies of Germany and of Great Britain, as well as in that of France. There is small blame to us if we err on the side of a too minute and pedantic regard for slight changes in breath sounds, or in percussion, for all the world is committing, or until recently has committed, the same mistake, and the standpoint is maintained by so many writers of repute that the unwary are scarcely to blame if they believe that it represents the standpoint of the truth.

One little good has certainly come out of the great mass of evil of this terrible war—that experience in the field has proved that men with slight, old, healed tuberculosis, or doubtful tuberculosis, do not need to be excused from military service, that most cases do well in active service, that they improve in health in the outdoor life, and consequently that our practice in peace has been in error in giving too great weight to slight indications of structural change. If a man presents himself for enlistment who shows slight old pulmonary changes, such changes should be viewed as evidence of bygone disease, cured, and, if the soldier is in vigorous health, to be disregarded in the decision as to his acceptance, and disregarded also in the record of his case, so that if it should unfortunately happen that the man in question should break down with active tuberculosis at a later time his disease will be regarded as incurred in line of duty.

*Read at the thirteenth midwinter meeting of the American Sanatorium Association, December 14, 1917.

Do not seize upon this admission of the possibility of such breakdown. Such cases may break down, but so also may men with athletic chests, and the breakdown of the latter is sometimes more serious and acute than that of the former. There is an unavoidable percentage of tuberculosis for which we must be prepared, which the most acute observer cannot foresee. Pardon me for repeating what I have said in part elsewhere.

The examinations for tuberculosis are conducted rapidly with a view to excluding active cases of the disease. Contraction of an apex, the changes being confined to the supra-clavicular region, is ignored; only cases of active tuberculosis, and those showing old lesions below the clavicle of some extent, are rejected. A ruling of this kind seemed necessary in order to prevent the exclusion of a large number of men in good health whose services the army needs. I do not need to say that such a ruling will not meet with favor in the eyes of many tuberculosis specialists. Already the Surgeon General receives letters protesting at the speed of the examinations (though without speed they could never be finished), and demanding that the slightest indication of even old tuberculosis shall be sufficient ground for the exclusion of the subject from the army. As a practical military proposition it is impossible to yield to such demands, and, as we have seen, the experience of the war shows that the demands are unjustified. I am an optimist as to the benefit of the outdoor life for the healthy men. Better than all others, we, as sanatorium physicians, know the benefits of such a life for the tuberculous. We do not perhaps realize fully how rude a health results from the outdoor life when led, under other hygienic precautions, by those who have not at the same time to resist the inroads of active disease. We moderns have, I believe, a wholly exaggerated idea of the dangers of fasting and hardship. In the time of the ancients, in the Middle Ages, among our Indians at the present day, that man was most esteemed as a warrior who could best endure hunger and thirst, cold and heat, and laborious days. They believed rightly that by such endurance the warrior became hardened and better fitted for the hand-to-hand combat that was his profession. And now that, in the round of time, combats have again come to be hand to hand, where strength, agility and endurance count as they have not hitherto counted since firearms were invented, our soldiers must be hardened athletes. There is, I believe, too much of a tendency to coddle them, to keep them filled with chocolates and to stuff their pipes with unending amounts of tobacco, to amuse them at all costs. Let us at least spare them undue anxiety as to the dangers of wet and cold and hunger; and let us, above all things, not hold before them the specter of tuberculosis as the inevitable result of warfare. As for the unfortunate prisoners of war, treated with unexampled brutality by their captors, that is quite a different matter. One may well despair who falls captive into the hands of the Germans. But it may be pointed out no selection at the time of entrance into the military service could have prevented such a result. The captives who become tuberculous do not break down with this disease because they already had it in active form on entrance into the army, but because insufficient nour-

ishment and bad hygiene can in time break the resistance of the strongest. We all have a little tuberculosis; that we resist it depends upon our fortune in avoiding depressing influences.

We need your confidence and help. I know that you are anxious to do all in your power to assist the Surgeon General, and through him the army and the people of the United States. You see the position of the military examiner. Here are enormous masses of men who must be examined without delay. When the National Army camps are finished we shall have examined about 800,000 men. Decision must be made quickly, yet the examiner must detect all active cases while careful not to reject obsolete or doubtful cases of tuberculosis. We know too well the difficulties of diagnosis in the doubtful cases. Some cases have come before the office for revision in which the army examiners were sustained against the opinion of leading men in the profession. In other cases we have been obliged to admit that the army examiners have erred, that as far as we could discover there was no activity of tuberculous disease. Only a fraction of such cases can come under our observation; there are doubtless many cases remaining that should have been excluded, as well as many good men who have been rejected without due cause. But we have done the best that we could; we have secured the best examiners available in the country. The standard, on the whole, has been very high, and, I would point out especially, the examination has been performed by army surgeons who but yesterday belonged to the civilian medical profession. The examinations constitute a revision of the work of the army medical officer in the examination of the recruit for voluntary enlistment, and of the work of the draft boards, and of the preliminary examinations of the conscripts at the cantonments. This is the court of appeal whose decision, however faulty it may be, is still the final decision. The Surgeon General wishes you to understand the difficulties under which we labor. I have set them forth as best I could.

Now, what can you do to help in this? You can sustain the hands of the Surgeon General by using your great influence with the public in a helpful way. You recognize the need of haste in the conduct of the examinations. Help us by sustaining the position that active tuberculosis can be quickly detected, and that it is not desirable that note shall be made of small, obsolete lesions; that experience in the field has shown that such cases do well in active service. And when the inevitable tuberculosis presents itself, whether because the examiners have failed, or because the tuberculosis had not developed clinically at the time of the examination, help the public to understand the situation. There will be unjust claims that the Medical Department has broken down, that the examinations have been a failure; take the broad view and teach the people that some tuberculosis must be expected. Above all, combat the widespread notion that trench warfare is deadly to the health, that our troops are doomed to be ravaged with tuberculosis. You have heard the views of Colonel Derle and of Major Rist; they represent the best thought of the French profession. Encourage the anxious parents to anticipate a robust health for their vigorous sons. Be optimists, and you will have deserved well of your country.

PSYCHOPATHOLOGY.*

BY EDWARD S. COWLES, M.D.,

NEW YORK.

THE subject of Psychopathology is one of so much importance that no attempt can be made to present it adequately here in the short time allowed for it. But a brief statement of some general principles involved in mental pathology may help to explain the nature of the group of mental disorders called psychoneuroses. For a correct diagnosis of such conditions the general physician needs a working knowledge of mental physiology. This must be the basis of a scientific psychopathology essential for rational treatment in accordance with the principles of general medicine.

In the progress of the medical sciences the provision in the schools and hospitals for the study and treatment of these cases is only beginning to receive proper attention in this country. The methods taught have been essentially objective, while the subjective methods which are vitally important in mental, psychopathological, or psychoneurotic cases have received but comparatively recent and limited recognition. In his clinical work the student is taught the refinements of the diagnosis of physical diseases. Such objective methods cannot in their very nature be employed in mental disorders of a functional character. Hence the physician with all his long years of training in our medical schools feels helpless in all cases of psychoneurosis, both in theory and practice. He is forced to fall back on drugs and other mechanical treatment without even so much as correctly diagnosing his case.

In the investigations of psychoneuroses the psychopathologist finds a strikingly clear pathological condition in each individual case. The symptoms of a psychoneurotic case are not isolated. They are intimately related. The symptom complex is grouped as a rule around a pathological nucleus which controls and guides the morbid manifestations. In a well developed case of "nervousness" the dizziness, faintness, nausea, acid stomach, etc., the headaches, the anesthesia and hyperesthesia, the fatigue, the abulia, insomnia, and general depression bear severally a definite relation to some pathological focus which the psychopathologist must find by a searching examination before an effective treatment can be undertaken.

The pathological focus of which I speak may more properly be expressed as a residual organic habit in the neurones or nerve cells. From this focus there develops the complex. One fixed idea associates itself with another idea until a group of ideas is formed—a complex, or idea-system, which may be in conflict with the main personality of the patient; and this conflict may be so buried in the subconscious mind that the patient himself may lose all recognition of its existence; and the functioning of this buried complex may produce a condition resembling in many ways a mild case of manic depressive insanity. That is, the patient may have days or weeks or months of apparently normal health when there breaks upon the consciousness a feeling of depression, of nervousness, of restlessness, an inner sense of excitement. With this the

patient's appetite is gone, an actual disgust for food may develop, accompanied by constipation or diarrhea. The buried complex may be expressed, as in a case reported, where the patient's mother had been for a long time at the point of death. She expected to get a telephone message at any time announcing the death of her mother. Consequently every time the telephone rang her heart jumped into her throat, as it were, and she ran to the telephone to get the dreaded news. After a while her mother died. But the association of the two ideas had become so fixed that whenever she heard a telephone ring her heart would palpitate, a thrill of nervousness would seize her, just as though she were to get the dreaded message.

A very important characteristic is the periodicity and remissions in the appearance of the symptoms. The attacks of functioning of the dissociated morbid idea-system may run in cycles. During the attacks the mind seems to run in a vicious circle. In many instances the attack is sharp, followed by a long period of depression and worry. It is pathognomonic of a psychoneurosis to have acute sensory attacks followed by long intervals of brooding. It matters little whether the cause of the brooding is conscious or subconscious. It is there, and the psychopathologist must uncover it if he wishes to diagnose his case clearly and introduce a rational therapeutic treatment.

Another symptom well worth considering in a certain type of psychoneurotic case is the sudden onset of the attack. The morbid mental state flashes on the patient's mind with terror for a brief period, sometimes for a moment like the *petit mal* of epilepsy, and then disappears as suddenly as it came, reappearing on some other unlooked for occasion. These occasions are not accidental. They have a definite causal relation to the attacks. Even here the periodicity of the attack is quite noticeable; in fact, it is so pronounced that some men describe the cases by the term "psychoepilepsy," others by the misused term "psychic epilepsy." These conditions should not be confused with epileptic states which are abnormal to the patient's normal associative life. They appear to the patient himself as dissociated from the rest of his interests, from the rest of his associations and psychomotor adjustments. He wants to extrude these dissociated states from his mind. He does not understand them. Often he is not even aware of them since they may appear subconsciously or completely overwhelm his personality during the entire period of their activity. These states are essentially subconscious dissociated states. They come in attacks manifesting extraordinary violence and emotional disturbances.

A very general characteristic of these morbid psychoneurotic states is the fact that they do recur with apparently the same content of consciousness and with the same almost invariable psychomotor reactions. The patient apparently thinks, acts, and wills in the same way on each occasion. These subconscious dissociated states really belong to the type of recurrent moment consciousness. The suddenness of the attack, the manifestations of the symptom complex so uniform, the overpowering effect on the patient's personal consciousness, are all due to the same underlying condition: the dissociation of

*Read before the Clinical Society of the New York Polyclinic Medical School and Hospital, October 1, 1917.

ideas in the patient's consciousness. The attacks can be traced to the mental trauma, emotional shocks, and especially to experiences of childhood. These early experiences that become subconscious may of course be other than those based on sex trauma as a principle (as urged by Freud, qualified by Jung, and newly interpreted by Adler), even when the early sexual experiences can be shown to have existed. Such experiences are easily exaggerated in the patient's mind as is often done, within my observation, in application of Freud's suggestive methods.

I need not discuss here the relation between brain activity and mind activity. It is enough to say that it is universally accepted that every mental process is accompanied by a physical process in the brain; that associated with every series of thought perceptions and feelings there goes a series of physical changes in the brain neurones. Likewise whenever the same series of physical changes occurs, the conscious series of mental processes, of conscious or subconscious states, arises. In other words, physical brain processes or experiences are related with corresponding mind processes or experiences. Upon this doctrine the whole of psychophysiology and psychopathology rests.

It is an accepted principle of physiology that when a number of neurones, involved, let us say, in a coordinated sensorimotor action, are stimulated into functional activity they become so associated and the paths between them become so opened, or, as it were, sensitized, that a *disposition* becomes established for the whole group, or a number of different groups, to function together and reproduce the original reaction when either one or the other is afterward stimulated into activity. In other words, without going precisely into the matter, it is sufficiently accurate to say that every mental experience leaves behind it a residue or trace of the physical brain process in the chain of brain neurones. These residua are the physical register of the mental experience; and this may or may not be conserved. If it is conserved we have the requisite condition for memory, but it is not until these physical registers are stimulated and the original brain experiences reproduced that we have memory. Prince speaks of such a condition in the term "neurogram." It is the organic habit of ideation. Of course memory must be thought of, as Prince has so aptly put it, as a "process of registration, conservation, and reproduction." Conservation of course implies registration but not necessarily reproduction. The psychophysiological memory must be considered because of the important part that such memories play in pathological conditions. Certain bodily reactions which are purely physiological, such as vasomotor, cardiac, respiratory, intestinal and digestive disturbances, become as the result of certain experiences linked with one or another psychical element: sensations, perceptions, thoughts. And this complex, conserved as a "disposition," the psychic reaction is reproduced whenever its physical element is introduced into consciousness. Here the association of an idea with the physiological process is conserved and reproduced. Such a reproduction is essentially a psychophysiological memory depending entirely upon the acquired disposition of the neurones.

At this point Pawlow's investigations are of interest to us not only as an apt illustration of the psychophysiological memory but of the important role the mind plays in relation to the digestive system.* The actual method employed by Pawlow in obtaining these results is so interesting that I feel constrained to give you a résumé. In his experiments upon dogs he was able by careful surgical methods to make a side pouch of a part of the stomach, the cavity of which was separate from the cavity where the food was received. It was supplied in the normal manner with nerves and blood vessels, and as it opened to the surface of the body it was possible to determine the kind and quality of the gastric juice secreted by it under varying conditions. Its secretions corresponded exactly with those of the main body of the stomach, and it had the added advantage of making possible the examination of the gastric juice unmixed with food. In some of the animals an opening was also made in the esophagus so that the food dropped out on its way to the stomach. The animal thus experienced all the pleasures of eating, and experiments could be continued as long as necessary without any discomfort to the subject. This was called sham feeding. By this method of sham feeding Pawlow showed that the chewing and swallowing of food pleasant to the animal was followed after a delay of about five minutes by a flow of gastric juice from the side pouch in the stomach; and this continued as long as the dog chewed and swallowed food and even for some time after the eating ceased. As there was no food present in the cavity of the pouch it is evident that the actual presence of food is not necessary for secretion of the gastric juice. And since this flow continued only as long as the dogs were hungry and enjoyed the food presented to them, the conclusion is justified that the secretion was truly a psychic one.

Sometimes the mere sight or smell of food was sufficient to start the flow of the gastric juice; this has been demonstrated by experiments of Bidder and Schmidt and later by Schiff. We all know the expression that the mouth "waters" in anticipation of food, and these experiments proved that the stomach may be said to "water" as well. This "watering" of the mouth, or initial psychic secre-

*Pawlow says: "In the course of our experiments it appeared that all the phenomena of adaptation which we saw in the salivary glands under *physiological* conditions, such, for instance, as the introduction of the stimulating substances into the buccal cavity, reappeared in exactly the same manner under the influence of psychological conditions—that is to say, when we merely drew the animal's attention to the substances in question. Thus, when we pretended to throw pebbles into the dog's mouth, or to cast in sand, or to pour in something disagreeable, or, finally, when we offered it this or that kind of food, a secretion either immediately appeared or it did not appear, in accordance with the properties of the substance which we had previously seen to regulate the quantity and nature of the juice when *physiologically* excited to flow. If we pretended to throw in sand, a watery saliva escaped from the mucous glands; if food, a slimy saliva, and if the food were dry—for example, dry bread—a large quantity of saliva flowed out, even when it excited no special interest on the part of the dog. When, on the other hand, a moist food was presented—for example, flesh—much less saliva appeared than in the previous case, however eagerly the dog may have desired the food. This latter effect is particularly obvious in the case of the parotid gland."

tion of the saliva, is important when we consider that materials can only be tasted when dissolved in the mouth and brought into relation with the organs of taste. Hornburg made observations of a little boy under his care which showed that food which he liked produced a more active flow of gastric juice than when the food was indifferent or distasteful to him. A similar result was obtained by some observations of Richet upon a little girl. All these observations show that if the taste of food is pleasant when it is being masticated the flow of the first digestive fluids, saliva and gastric juice, is favorably stimulated; and the same is true when, in anticipation of eating, the sight and smell of the food are such as to inspire the desire to taste it.

This brings us to the point of considering directly the influence of the mind pathologically on the digestive system. A paragraph by Dejerine is a striking description of this:

"It sometimes happens that a physician has patients—they are more apt to be women—whose appearance is truly shocking. Their eyes are brilliant. Their cheeks are hollow, and their cheekbones seem to protrude through the skin. Their withered breasts hang from the walls of their chests. Every rib stands out. Their shoulder blades appear to be loosened from their frame. Every vertebra shows through the skin. The abdominal wall sinks in below the floating ribs and forms a hollow like a basin. Their thighs and the calves of their legs are reduced to a skeleton. One would say it was the picture of an immured nun, such as the old masters have portrayed. These women appear to be fifty or sixty years old. Sometimes they seem to be sustained by some unknown miracle of energy; their voices are strong and their steps firm. On the other hand they often seem at the point of death and ready to draw their last breath.

"Are they tuberculous or cancerous patients, or muscular atrophies in the last stages, these women whom misery and hunger have reduced to this frightful gauntness? Nothing of the kind. Their lungs are healthy; there is no sign of any organic affection. Although they look so old, they are young women, girls, sometimes children. They may belong to good families and be surrounded by every care. These patients are what are known as mental anorexics, who, without having any physical lesions, but by the association of various troubles, all having a psychic origin, have lost a quarter, a third, and sometimes a half of their weight. The affection which has driven them to this point may have lasted months, sometimes years. Let it go on too long and death will occur either from inanition or from secondary tuberculosis. However, it is a case of nothing but a purely psychic affection of which the mechanisms are of many kinds."

A typical case of this character is cited by Dejerine, of a woman who had lost her husband. She grieved for him deeply and continued to live in the apartment which they had occupied together. He says:

"When she sat down to her meals his image would rise up before her, as would be natural from the association of ideas, bringing a whole train of emotional sensations, constrictions of the throat, a feeling of weight in the stomach, lack of appetite, etc. She would get up from the table without having really eaten anything. By degrees this restriction of diet, which was purely emotional in its origin, brought her at last to the condition of mental anorexia."

In my own practice I was once called to see a patient of this type, a woman who in early life had loved a man and had borne a child by him. He had run away from the town without marrying her. She came to think of her conduct as a sin. After the child was born she married and had other chil-

dren, but none so dear to her as this first son. The memory of her early irregularity remained with her as a sin. She constantly tried to repress it by turning her mind away from it. When well and strong this was easy, but when tired the memory came back with increasing force and was more difficult to keep out of consciousness. It became a pathological nucleus, separated from the main current of normal consciousness and thus dissociated from it. When this process of repression had been going on for a long time, with increasing difficulty in times of fatigue, a revivalist happened to come to the town, preaching brimstone and hell fire. This awakened the memory of her supposed sin with redoubled force. She could fairly see her son burning in hell and feel the added punishment that would come to her for having brought him into the world under such irregular circumstances. She was completely upset. She had no taste for food. Her rest was broken by painful dreams. Her stomach and bowels were deranged, her emotions on edge, her heart beating wildly and furiously at times. Being a strong, healthy woman with much work to do, she successfully repressed the idea. When busy and active she would not seem to think of it, but it seemed always there, and a moment's relaxation would bring it into consciousness and it would gnaw at her heart strings.

This condition went on till her son became a man. Early in life he had developed the drink habit, and later on a serious heart trouble. One day on a drunken spree he came toward her, and when within a few feet of her he stumbled and fell dead of heart failure. This she interpreted as the visitation of God's wrath upon her for her sin. It was not merely the loss of her son, but that she, as well as her son, was punished and that both of them would be committed to everlasting punishment. Still being strong she was able for a few days to keep up, to wrestle with her overwhelming consciousness of sin and damnation, but the grief over the loss of her son, over her previous "sin," over God's wrath, had so multiplied itself in her mind as to completely overwhelm her. Even to see a young man would cause her to faint. She refused to eat and was finally put to bed. She lost flesh rapidly, suffered from loss of sleep, from the emotion of excitement, from constipation which later turned into a most violent form of diarrhea. She was sent from one sanitarium to another, from one set of physicians to another. Every effort was made to build up her digestion and to control her diarrhea. Medicine seemed to have no effect. She was at the very threshold of death from exhaustion. After a consultation with her physicians the diagnosis seemed plain. The hyperexcitement of her nervous condition was allayed, the simplest sort of suggestion was given, and in less than a week the diarrhea was under control, and her digestion and assimilation were restored to normal.

Another case was that of a young woman of culture and refinement. She had been healthy all her life, but at the birth of her second child she had some slight trouble which reduced her energies to some extent. She thought she had some form of intestinal disease. She consulted her physician and then passed from one physician to another; one formula after another was given her till she was

taking practically nothing but toast and milk. She had developed a very severe mucous diarrhea. A laboratory examination was made of her stools, and in spite of the fact that the microscope showed considerable trouble my treatment was insisted upon as of a mental condition of expectant attention. When her mental condition was brought into proper relation to her digestive system, when the hyperexcitation of the neural disposition had been reduced, when the psychic tension arising through organic disposition and expectant attention had been allayed, her diarrhea disappeared. This happy change was effected in less than six weeks although when this treatment began she had been suffering from her trouble for five years. The organic habit or disposition was dissipated.

The method remains the same in many dyspeptics having the different symptoms of eructations, vomitings, pain and heaviness in the stomach, dilatation, and gastropnoia. It is the stomach suffering from the effect of the nervous condition. The cause of this form of nervousness is not located in an organ; it is mental. Dubois goes so far as to say that 90 per cent. of dyspeptics are psychoneurotics, and that these patients should have nothing to do with restricted diet and stomachic medication. This opinion has been largely proven in my experience.

There is a host of dyspeptic patients, says Dubois, who haunt the health resorts, forever discussing their symptoms, never able to eat anything yet always in pain. Their stories are similar; they have usually begun by treating themselves, cutting out from their diet foods popularly supposed to be indigestible, such as cabbage, for instance. Conditions would appear to improve for a time, then fresh disturbances would set in and further restrictions in diet, followed again by a new temporary improvement but an added failure. At about this point a physician is usually called in who tries, let us say, washing out the stomach. The patient may now imagine that he has dilatation of the stomach. The course of treatment becomes more and more severe. A specialist is consulted. He may not admit the dilatation but tests it by insufflation and analyzes the contents after a test meal. If these show nothing definite the patient will be classed as "nervous," and usually is sent away for rest and change. Mechanical methods will be resorted to a greater or lesser degree, and the patient stands a chance of improvement. But if an excess of mucus is found, or hyperacidity, or retention of food, then the patient is apt to become the victim of a series of experiments which are only limited by the personal theories of the attending physician. One will prescribe an exclusive diet of milk, another will forbid milk as if it were poison; one will insist upon uncooked foods, while another will demand added hours of cooking to make the food fit for digestion. The patient may be condemned to lavage of the stomach; massage may be prescribed, or electricity; douches may be given on the epigastrium. When all these measures fail to bring relief he may be given tonics and beef juice, raw eggs and wine and phosphates. Watching these successive experiments fail, hopeful of each new experiment only to see it fail in turn, the patient becomes more and more impressed with the seriousness of his case,

and his hypochondria becomes more and more fixed as the physician directs his attention more and more to this or that supposedly diseased organ. The patient's mind needs to be treated and directed from his bodily discomfort. The cause of his trouble is mental, not physical.

In order to diagnose these cases correctly it is necessary for the physician to see the man as a whole, not alone his disturbed physical functions. The factor primarily important in the treatment is to regulate not so much what the patient shall eat or drink, but what he thinks. The whole man must be treated, his whole personality worked upon, and when the cause of the mental disorder has been removed the physical disturbances will of themselves disappear. Want of time forbids me even to mention the many and varied forms of stomach and intestinal disorders directly due to mental and emotional disturbances.

By the terms obsession, compulsion neurosis, anxiety neurosis, or complex, I shall understand any recurrent extra-voluntary idea, feeling or emotion which presents itself automatically in the consciousness, either alone or in combination. We are interested really in the mechanism of these phobias, the manner in which they arise, and the factors by which they are perpetuated. The underlying principle of them all—obsession, compulsion neurosis, anxiety neurosis—reduced to its simplest terms, is really fear manifesting itself pathologically in one form or another. In fact, every obsession has its history, just as a painting has, or a poem, or a symphony. These obsessions arise from conflicts in the consciousness, form complexes, and are dissociated or split off from the main stream of consciousness. The patient's mind is in a state of conflict with itself. A battle royal is going on between the fear complex and the main body of his personality. Whether an obsession appears in consciousness as a complex whose nucleus is an idea, a feeling, or an emotion, it originally arises out of the same psychological mechanism: dissociation. I may say that dissociation and association play equally important roles. When once an obsessional complex has been established it may be aroused to activity in a great many different ways.

For instance, a patient of mine, during a severe attack of grippe, was surprised on one occasion to find that she had lost control of her bladder, and was greatly shocked by it. The idea flashed into consciousness, "What should I do if this should happen at some entertainment?" She repressed the idea as unpleasant and tried to put it away, to forget it; not realizing, of course, that the more she fought the idea and the more she tried to repress it, the more rapidly it would grow from a small nucleus into a complex always ready to torment her. These painful ideas that the patient tries to forget, tries to repress, tries to put out of consciousness, are not really forgotten but stand ready to spring into consciousness when the patient is tired. This patient did apparently forget this particular incident, but several months later when invited to a party she found herself very apprehensive about going—nervous, excited, her heart palpitating, and feeling the necessity of emptying the bladder several times before leaving the house. Then she imagined a real pressure, a sense of irritation in the bladder; she

fancied she had a bladder disease. She was treated for this condition locally, her bladder washed out, etc., with only temporary relief. This fear increased in intensity; the mental excitement intensified her emotions, upset her stomach, disturbed her digestion, and deranged the glandular functions; all this taken together produced severe headache and depression. She was then in a state of nervous prostration. Even the thought of going anywhere would awaken the memory of her former feelings of distress, creating a panic. The fear had changed to a fear of fear. To speak of going out of her room, of visiting, of traveling, caused her the greatest distress without her apparently remembering the loss of her bladder control. When I first saw this patient she had been suffering from this trouble for more than twenty years. The trouble with her bladder was removed from her active consciousness, having lost itself in the great complexity of symptoms that had arisen from it originally. Although in a state of utter prostration, unable to take any substantial food, in the depths of depression and despair, this woman under proper treatment made a complete recovery in two months.

An obsession of different character is that of an able-bodied man, best described by quoting from his own letter:

"I am a strong, robust man, aged 44. Fifteen years ago I was standing in a rather close room with a party of friends when I was suddenly seized with a faint feeling, an all-gone-ness in my stomach. A deadly fear seemed to come over me. From that day for over fifteen years I was an invalid. I was treated for months by the best physicians I could secure, without relief, and finally gave up in despair. I was afraid of everything. I could not meet my friends downtown, could not go into a closed room, could not ride upon a train, could not meet people at dinner, would run and hide if I even saw my best friends coming. I could not let my wife leave the house without being seized with a convulsive fear. The very thought of meeting people or riding on a train would cause the severest form of headache and diarrhea. The fear was so overpowering that I could not have gone to the doctor's office if he had offered me a million dollars, badly as I needed the money."

This patient was first visited at his house. His intense suffering was clearly evident; deep black circles surrounded his eyes; his whole physical condition seemed thoroughly toxic from the fear upsetting his emotions, deranging his digestion, and interfering with the normal functions of the internal secreting glands. After two visits in his own home he was able to come to my office, and in three weeks had completely recovered.

Another case was that of a girl quarantined in school because of an epidemic of smallpox in the community. A letter was received at the school which created a fear that it might carry infection. This girl developed a mysophobia, and the fear of infection caused her to wash her hands continuously; she washed them until they bled. The fear spread to everything. She would not touch a door knob or open a letter, or even allow letters to be delivered at the house. She cried whenever fresh air was let into the room for fear germs would be admitted. Eventually after fifteen years she became a helpless invalid, and finally had developed a marked functional heart trouble. Her legs were much swollen. I mention this because under treatment when she was cured of her fear her physical condition became normal. This patient recovered

her health, and in less than a year took a course in manicuring and hairdressing, and established herself in a lucrative business.

There comes another type of the fixed idea. This can better be described by a concrete example of an old lady of eighty. She had been putting down a carpet one day and held some tacks in her mouth for easy use. She suddenly felt a twinge of pain in the side of her tongue and supposed a piece of tack had gotten into it. She hurried to her doctor's office, where he examined her carefully, told her there was a little sore place there, but he could find no evidence of the tack. He thought he could help her by the use of the violet ray. This he used for some time, the old lady all the time suffering violent pain in her jaw and tongue. After several weeks of treatment without help she went to another doctor, who gave her medicine, but did not help her. Another doctor performed some slight operation which gave her apparent relief for a few days, the pain returning with redoubled force. When this patient first came to me she had been suffering for about four years with her tongue and jaw, which were actually swollen, and on the outside she had blistered and reblistered her face. She would walk the floor in agony night and day. The pain was almost immediately controlled, and this woman was well, even at her age, in six weeks. She lived to be 87 years of age without having any recurrence of her trouble.

As you see, there are many varieties of the instinctive fear psychoses. Great progress has been made in the study of these affections in recent years. The views so briefly given here are not new; it was my fortune to be taught when a medical student at the Harvard Medical School to make the widest application of the underlying general principles to all reactions of emotional feeling combined with their physical complexes. The associative principle so applied makes clear a broad summary of these fear and other emotional affections. They occur in distinctive groups: the *objective* obsessions including fears of inanimate things incapable by themselves of doing any harm by intention—such as lightning or high places—or of naturally irresponsible living things, such as animals; the *subjective* fears of affections or disorders of the body which are known as hypochondriacal fears and hysterias. It was taught also that the same principle is taught *objectively* when fears attach themselves to the actions of other persons capable of intention, thus explaining the genesis of suspicions weaving themselves into systematic delusions of persecution, constituting paranoia or paranoid conditions. This principle, having a primary influence in the essential unit association of *concept*, *emotional reaction* and *motor effects*, these effects may be wholly subjective or be manifested outwardly in behavior, both in normal and abnormal conditions. In the treatment of the special disposition to these mental and somatic complexes in the involution psychoses there is increasing proof of the need of recognizing the principles of psychopathology and the value of psychotherapy.

In this connection I should make mention of the more profound traumatic neuroses of which Dr. Sharpe sees so many in his field of work. The subject is of timely interest because of the large num-

ber of persons suffering from traumatic neurosis incidental to the present war. I can only refer to this large class of cases and quote briefly what Oppenheim has to say as reported by Mayer:

"There is no doubt that the finer organization of the nervous tissue can be directly and indirectly injured without the occurrence of hemorrhage, inflammation, degeneration and necrosis. I refer to finer physical occurrences. The influence of this overestimated impulse seems to me like the removal of a link in the chain, or of the displacement of the molecules, or of an inhibition of tracts, a tearing apart of associated functioning parts, a diasthesis—in short, a condition which is not microscopically demonstrable, which does not represent definite alterations of nervous tissue, but which in every case produces inhibitions to motor impulses."

And Wilson, also quoted by Mayer, sets up the following explanation:

"1. At the synapses there is a structural discontinuity of the nerves. 2. The results produced by impulses traveling in a nerve depend on the way the fiber ends, and not on any differences in the impulses themselves. 3. At the synapses different physiologic systems come in touch with one another and so co-ordinate action in diverse systems is possible. At the synapses there is always a spread of nerve impulse, and the greater the impulse the greater the spread."

It may be possible that the study of the traumatic neuroses, shell shock, etc., may be the means of helping medical men see the psychoneurotic cases less fantastically and more as a *mixed condition of nerve cell exhaustion and mental conflict*. The matter may prove to be really a psychophysiological problem, expressing itself pathologically.

15 EAST FORTY-EIGHTH STREET.

RESTORATION OF MOTOR FUNCTION IN A RESECTED NERVE TREATED BY END-TO-END ANASTOMOSIS WITH REMOVAL OF CONSIDERABLE NERVE TISSUE.*

By J. BYRNE, M.D., A. S. TAYLOR, M.D., and
S. W. BOORSTEIN, M.D.,

NEW YORK.

THE tremendous number of nerve injuries received during the present war has afforded many opportunities for neuroplastic surgery. Old operations have been modified and new methods devised. When one follows the voluminous literature of that branch, recently published, he is favorably impressed by the excellent results, though it can be inferred that the cases have not been followed up afterward by recording and charting the anatomical return of function in the resected nerves. We must agree with Frazier,¹ who says: "The European war has revived our interest in the problems of dealing with injuries of the peripheral nerves and

*From the Neurologico-orthopedic department of Fordham Hospital, New York. The operation was performed by Dr. A. S. Taylor, the neurological surgeon of the hospital. The details of the operation have been described by him. The orthopedic care and after treatments were carried out by Dr. S. W. Boorstein, orthopedist of the hospital, who also wrote the history and the details of the after treatments. The neurological examinations and the chartings and tracings were done by Dr. J. Byrne, the consulting neurologist of the hospital. The latter also wrote the neurological discussions. The case was presented before the Orthopedic Section of the New York Academy of Medicine, March 16, 1917.

while numerous contributions have appeared in literature, sufficient time has not yet elapsed for a general 'round up' and conclusions at this time can only be surmised. Many interesting observations have been made during the war did we but have time to discuss them."

Being fortunate enough to study and chart carefully a case of a resected nerve from the time of operation to the time of almost complete return of function, we feel that it is of extreme importance for the neurological surgeons to have the benefit of this study. This may be of considerable use to them in their work. Their limited time at present does not permit them to make similar studies. We are, therefore, reporting this case, giving the history and findings in detail, adding only casual comments in the findings. The facts are clear enough without reviewing the literature.

On October 15, 1914, the patient, H. G., a young student of 22, while playing football attempted to make a catch while an opponent tackled him around the waist. The patient was thrown to the ground and received an injury to the left leg. The head of the fibula was pushed outward (dislocated laterally) but the tibia remained in place. The bone was replaced on the field but the patient could not walk home. In a day or two the knee became swollen and tender and he had to be confined to bed for five weeks. By that time the swelling and pain subsided, he began to walk but noticed that he limped, had a drop foot and as he expressed it had no control of the movements of the toes and even had very little sensation in them. Five months later, March, 1915, he came to the orthopedic clinic of Fordham Hospital for relief of these symptoms.

Physical examination showed paralysis of the peronei and tibialis groups. The extensors of the toes were completely paralyzed and there was marked atrophy of the calf and foot muscles. The x-ray picture taken to determine the presence of fracture was negative. Myotatic irritability was present in all four muscles (tibialis and peronei) but considerably diminished as compared with the sound leg, more especially in the peroneal group. A diagnosis of injury to the external popliteal nerve was made. Believing that the nerve was beginning to regenerate we advised conservative treatment.

An ankle brace with a stop joint (allowing full dorsal flexion but no plantar flexion) was put on and massage and exercises were ordered. This was carried out for two months *i.e.*, till May, 1915, with slight improvement in sensation. Neurological examination made May 3, showed:

1. *Motor*: drop foot, steppage gait, inability to flex foot or toes dorsally, atrophy of calf three quarters of an inch with swelling one quarter of an inch over instep. Myotatic irritability well marked in anterior tibial and peroneal groups. (Paralysis of all foot muscles was thus found).

2. *Sensory*:* A. Spontaneous phenomena—numbness on outer aspect of leg and dorsum of foot; occasional feeling of pins and needles on dorsum of foot near roots of toes and about ankle.

B. Elicited phenomena are shown in chart A. The loss for intermediate degrees of heat and cold (38° and 25° C.) corresponded roughly with that for light touch after shaving (lighter von Frey hair used). Along the outer aspect of the foot, the extent of loss for prick with weak and strong stimuli (algometer at 2 and 12 grams pressure) corresponded closely with loss for light touch. This was in marked contrast with the inner aspect of the foot where the loss for light touch was considerably greater in extent than that for prick at 12. No over-reaction was elicited by prick or the dragged pin point with the exception of a mere trace at the roots of the first and second toes.

An operation was then decided on, which was per-

*All the tests done on this case are quantitative determinations as the patient was an intelligent subject and the results are thus reliable.

formed by Dr. A. S. Taylor. At the operation, May 4, 1915, it was found that the nerve at the head of the fibula was imbedded in a mass of fibrous tissue for a distance of 2 to 2½ cm. A section of the nerve (2½ cm.) was removed and an end-to-end anastomosis performed by carefully coapting the ends where good bundles were found and using a layer of fascia to prevent adhesions. Fine chromic catgut was used as suture material. The nerve was not freed for any longer distance. The knee was put in acute flexion to allow complete nerve union. Skin was united by first intention.

The nerve tissue removed was examined by Dr. John H. Larkin, who reported that "The mass consists mainly of connective tissue. Few healthy fibers are present and there is only slight evidence of attempts at regeneration."

On May 11 (one week after resection of the nerve) the sensory loss in the foot was the same as on the day before operation. It is interesting to note that pressure touch with the unweighted esthesiometer was present all over the foot. Rivers and Head² record similar findings after section of the external cutaneous branch of the radial nerve in the arm. Myotatic irritability in

On September 1, 1915 (four months after the operation) patient could extend the four toes and flex the foot slightly dorsally. The adduction power likewise was beginning to return.

On November 7, 1915 (six months after operation) the improvement in the motor power had increased especially in the tibialis anticus. The peronei had not improved much at the time but the patient could flex the foot dorsally quite well. The calf showed one inch of atrophy but the foot showed only one-eighth of an inch of swelling. The flexor brevis digitorum supplied by the tarsal branch of the anterior tibial, was markedly atrophied with no trace of myotatic irritability. The limb was cold. The sensory loss was as shown in chart B. The added area of impairment for light touch, chiefly above and posterior to the original area, was the result of injury of the lateral and other cutaneous branches of the external popliteal at the operation. The

Fig. 1

Fig. 2

Fig. 3

Fig. 4

CHART A.—Sensory chart made May 3, 1915, before operation. Area bounded by heavy dots, sinking to plantar surface between toes at the web shows absolute loss for the lighter von Frey hairs; it shows also loss for intermediate heat (33° C.) and cold (25° C.). Area bounded by lighter dots shows relative loss for light touch. Area bounded by dashes shows absolute loss for prick with algometer at 2 grams pressure. Area bounded by dots and dashes shows loss for prick with the algometer at 12 grams. Area bounded by dashes shows also area of loss for gross heat (55° C.) and cold (ice). Figs. 1 and 4, anterior view of dorsum; Fig. 2, lateral aspect; Fig. 3, mesial aspect.

the anterior tibial and peroneal groups was present but considerably impaired in comparison with the sound side. On May 14 (ten days after section of the nerve) myotatic irritability in these groups had become considerably enhanced.

The patient remained in the hospital for four weeks and was transferred to the orthopedic clinic. We then began to stretch the knee gradually, placing it in plaster and changing this every week. At every sitting the knee was stretched till the patient asserted that there was a sensation of pain as if pricked by a needle.

On June 4, 1915, (one month after nerve section, faradism evoked an exaggerated sensation within the area of touch loss as compared with the sound side. The galvanic current at 5 milliamperes showed a good response. In the peroneal and anterior tibial groups, KCC being greater than ACC. No response to faradism.

On July 1, 1915 (two and one half months after operation) the knee was straight and the brace was re-applied allowing the patient to walk. At the same time, electricity, massage, and muscle training were ordered. The findings at that date showed the sensory loss in the foot was about as on May 3.

irregular sinuous saw-tooth curve of the line bounding the areas of loss for light touch and prick is characteristic of the regenerative period after nerve suture. The shaded areas represent partially returned sensibility for prick. These areas were located (a) about the middle of the area for prick loss on the outer aspect of leg and (b) proximal to the roots of the toes. The area on the leg may have borne some relation to the overlapping nerve supply (external popliteal and its external cutaneous branch) in this region.³ The brace was then changed for a more simple one which would not cause so much atrophy. He was also advised to use the foot for two to three hours daily without the brace.

In February 17, 1916, 9 months after operation, patient was able to flex the foot dorsally to an angle of 100°. Had fair power in the peronei and tibialis and increased motion in the toes.

In April, 1916 (less than a year after the operation), the patient was able to walk without the brace. In June he even played baseball. He found that he could walk without a limp but on running there was a slight limp. The brace was discontinued July, 1916.

On December 10, 1916 (19 months after operation), the sensory loss was as shown in chart C. Sensibility

for prick (algесimeter at 2 and 12 grams pressure) had returned everywhere. Localization for prick was fair in places where sensibility for touch (heavier von Frey hairs) had returned but no over-reaction or radiation was observed anywhere. The small circles on the foot indicate points of returned sensibility, the two lower areas for the finer, and the two upper ones for the coarser von Frey hairs. These spots showed variations in sensibility from day to day. In these tests, made during the cold weather, the feet were first "warm adapted" by immersion in warm water for some time.*

On June 24, 1917 (nearly 25 months after operation), the motor power in the anterior tibial and peroneal groups showed a slight weakness as compared with the sound side. The calf showed three-eighths of an inch of atrophy. Myotatic irritability was present in these groups, the response being almost equal to that on the sound side. The belly of the extensor brevis digitorum

that in which heat at 38° C. was absent. The temperature of the room was 25° C. the day being fine and warm, the relative humidity being low. On the dorsum of the foot the compass tests (points simultaneously applied) showed marked impairment e.g. at 2 cm. right

side $\frac{1}{2} = \frac{10 \text{ right}}{10 \text{ right}}$, left side $\frac{1}{2} = \frac{\quad}{2 \text{ right, 8 wrong}}$.

For the points consecutively applied the record showed almost perfect answers. The tuning fork showed some impairment over the affected limb. Prick at 2 and 12 grams was present all over but slightly impaired in comparison with the sound side. No over-reaction, but stimuli applied upon a small area (2 inches below the lower border of the head of the fibula) were referred to the dorsum of the foot and the roots of the toes. This held also for gross heat and cold (55° C. and ice) but not apparently for pressure pain. Pressure pain showed

CHART B.—Showing the sensory changes on Nov. 7, 1915 (6 months after resection and suture of the external popliteal nerve). The external cutaneous and other branches have added their quota to the sensory loss. Area bounded by heavy dots shows absolute loss for light touch using the lighter von Frey hairs. Area bounded by stippled shading relative loss for same. Area bounded by dashes absolute loss for prick using algесimeter at 2 grams pressure; it also shows loss for gross heat and cold (same as for prick loss). Area represented by linear shading on lower part of leg and above roots of toes represents returned but impaired sensibility. E represents operative scar; F represents areas in which various forms of stimuli evoked correct specific sensations which were referred to various areas about the roots of the 1st, 2d and 3d toes; Fig. 5, anterior view of foot; Fig. 6, mesial aspect; Fig. 7, lateral aspect; Fig. 8, posterior aspect.

was markedly atrophied and no response could be elicited by tapping though ready response was elicited on the sound side. There were no spontaneous sensory phenomena and the two limbs seemed equally warm to the patient and to the examiner's hand. The loss for the lighter von Frey hairs was of slightly greater extent than that shown for the heavier von Frey hairs in chart C (localization being markedly impaired). The line of change for the dragged pin point corresponded closely with the boundaries of light touch loss set forth in chart C. Heat at 38° C. was absent over an area that corresponded closely with that bounded by the line of change. Cold at various temperatures ranging from 23° to 29° C. was felt all over the limbs. At 30° C. cold was absent over an area corresponding closely with

no material alteration in a series of tests with the algесimeter. On July 13, 1917, myotatic irritability was present but slightly impaired in the anterior tibial and peroneal groups. In the same groups there was a good though somewhat impaired response to faradism and galvanism. No response could be elicited in the atrophied extensor brevis digitorum by faradism and galvanism or by mechanical stimulation. For comparison we reproduce here in chart D a case of musculospiral paralysis. Compare the dorsal views of the foot and toes in chart A.

Comments on the Findings in This Case.—From the neurological aspect these features are interesting:

1. The site of original injury to the nerve was

*Since presenting the case two additional notes viz. June 24 and July 13, 1917, were made.

below the origin of the external cutaneous branch. The area of sensory loss is shown in Chart A. Resection of the nerve at operation did not alter the boundaries of this area upon the foot, but superimposed a new area of loss enlarging the original area upward and posteriorly on the limb. The external and other cutaneous branches of the nerve were evidently involved at or after the operation (the added areas of sensory loss corresponding to the distribution of these branches (see Charts B and C).

2. The external popliteal nerve bears a close analogy to the radial branch of the musculospiral in the arm. Careful sensory tests with measured stimuli showed that the sensory distribution on the

Contrast the hyperalgesia (causalgia of Weir-Mitchell) and the intense suffering which follow untreated wounds of the nerves and imperfectly performed nerve resection and suture, especially where the injured limb is subjected to prolonged immobilization.

4. Well marked allocheiria was present during regeneration, *e.g.* stimuli such as cold at 20° C. applied upon areas of defective sensibility about the level of the head of the fibula were appreciated correctly, but were referred to the region of the roots of the great toe and its immediate neighbors. It was in this latter region only that anything like over-reaction to painful stimuli was obtained at any time. This fact has an important bearing on the

Fig. 9

Fig. 10

Fig. 11

Fig. 12

CHART C.—Area bounded by heavy dots shows loss for light touch, using the lighter von Frey hairs; it shows also marked impairment of compass tests, points simultaneously applied; it shows loss for intermediate heat and cold (corresponding roughly with area of loss for light touch); and it shows also line of change for dragged pin points. Area bounded by dashes shows loss for the heavier von Frey hairs. Prick with algometer at 2 and 12 grams; sensibility present but impaired everywhere. No over-reaction or radiation. Gross heat and cold were felt everywhere but sensibility impaired; G represents area of returned sensibility for the lighter von Frey hairs; K represents area of returned sensibility for the heavier von Frey hairs. A second "line of change" of sensation is represented by the finely dotted line running downward and backward from the operative scar (E), corresponding probably with the bounds of distribution of the external cutaneous branch. Fig. 9, anterior view of foot; Fig. 10, mesial aspect; Fig. 11, lateral aspect; Fig. 12, posterior aspect.

dorsum of the foot also on and between the toes corresponds exactly with the distribution of the radial nerve upon the hand as found by one of us (Byrne) in several cases of section and suture of the radial nerve and of its branches supplying the dorsum of the hand. Compare Charts A and D.

3. There was almost complete absence of spontaneous pain and of the annoying discomfort and over-reaction incidental to the stage of recovery when "protopathic" sensibility is the predominating feature. The painless recovery is to be attributed to the orthopedic after-treatment (massage, judicious exercise, etc.), and the accurate adaptation of the fragments, primary union, manipulation, etc.

question as to the mechanism of allocheiria, referred and reflected pain, etc. Discussion of this question is reserved for a future communication.

5. Before resection of the nerve, April 28, myotatic irritability was present, but impaired as compared with the sound side, in the anterior tibial and peroneal groups. Thus tapping these muscles caused no appreciable response in the foot, toes, tendons, or muscles. Ten days after the operation, May 14, myotatic irritability was markedly increased, tapping the muscles causing well marked contraction with movement of the foot, tendons, and toes (dorsal flexion, etc.) Six months later, Dec. 25, no definite response to tapping the muscles of

this group in either leg could be elicited. At this time, however, the patient was, of course, up and around, and had walked a great deal just before the tests were made. Schiff¹ states that muscle irritability always increases for some time after section of the motor nerve. It is well to remember that the muscles of the outer aspect of the leg, like those of the radial side of the arm, may have a supplementary motor nerve supply coming from the nerves supplying the flexors.

6. The delay in full restoration of "epicritic sensibility," as shown by examination, nearly 26 months after suture of the nerve is a usual occurrence as is marked variability of the "epicritic sensibility" with weather conditions (cold weather impairing and warm weather enhancing sensibility). The appreciation of cold at all degrees below 30° C. shows that no hard and fast limits can be laid down for the epicritic ranges of temperature. The tem-

Fig. 13

Fig. 14

CHART D.—A case of musculospiral paralysis following fracture of the humerus for comparison with our case. Area bounded by heavy dots shows loss for the lighter von Frey hairs. This line sinks to the palmar surface between the thumb and index finger and between the index and middle fingers. This corresponds to the loss for light touch after section of the external popliteal nerve, Figs. 13 and 14. Compare Chart A, Figs. 1 and 4. Area bounded by dashes shows loss for prick with algometer at 2 grams pressure. In this case neuroplasty was performed and motor power began to appear in the extensors of the wrist 15 months after the operation. Return of cutaneous sensibility was somewhat irregular and retarded as compared with the case now reported. Fig. 13, palmar surface; Fig. 14, dorsal surface.

perature of the part to be tested is, of course, a factor that always demands consideration. The test, however, made in June 24, 1917, with carefully dried tubes, etc., seem to show that Head's range for epicritic cold, viz., 25° to 27° C., must not be regarded too literally.

7. The rapid recovery of motor function was remarkable even after making due allowance for the proximity of the muscles innervated. This must be attributed (1) partly to the orthopedic treatment (protective apparatus, etc.) from the beginning which prevented overstretching of the toneless muscles and kept the muscles in the optimum condition for functional reunion with the regenerating axone processes, (2) partly to the perfected technique of the neuroplasty, and (3) to the proper use of the muscles.

8. Cases of nerve injury with paralysis of the

muscles should be looked after from the beginning to prevent overstretching, deformity, etc., and where the symptoms, sensory or motor, do not clear up in a short time, *e. g.* in two or three weeks, exploratory operation is indicated.

9. At present many of these operations for injuries of the peripheral nerves caused by bullets are performed at the base hospitals and excellent results are reported. In civil life, on the contrary, such operations are usually neglected. These cripples are sent to the orthopedists and some orthopedic operation is done on the joints. If we can get such improvement after a delay of nine months from injury to operation how much better are the chances if we are able to perform the operation immediately after the injury? We feel certain that in a case where a suspicion of an injury to a peripheral nerve is present, an exploratory incision is justified. The nerve can be inspected and if found intact nothing has been lost. There is only the skin to be closed.

Conclusions and Summary.—1. In any case where an injury to a peripheral nerve capable of causing permanent loss of function is suspected, an exploratory incision is justified.

2. Good results can be obtained in suturing nerves even if a considerable time has elapsed between the injury and the operation.

3. Even a gap of 2½ cm. can be bridged by stretching the nerve gradually and there is no need of nerve grafting or resecting the nerve for some distance.

4. Pain is absent in straightening and using the limb subsequent to the operation if this is done gradually.

5. The motor function returned quite early while the sensory return was slow.

6. Orthopedic treatments are necessary after operation to prevent stretching of the denervated muscles while the regeneration of the nerve is taking place. An overstretched, denervated muscle will not readily recover its normal length or tonus.

DERMATOSES OF THE SCALP.*

By MOSES SCHOLTZ, M.D.,
CINCINNATI, OHIO.

CHIEF OF CLINIC AND INSTRUCTOR OF SYPHILOLOGY AND DERMATOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF CINCINNATI;
JUNIOR DERMATOLOGIST OF JEWISH HOSPITAL.

CLINICAL material of any specialty in medicine can be classified in several different groups, according to the viewpoint taken as a basis of classification. Thus cases can be divided in groups according to their pathology, etiology, morphology, or according to their subjective, symptomatological, therapeutic, or any other characteristics. Topographic or regional classification has proven its clinical usefulness on many occasions. It is frequently adopted by

*Read before the West End Medical Society of Cincinnati.

surgeons who find it practical and serviceable to consider, as a clinical unit, surgery of a certain part or region of the body, such as surgery of the head, chest, joints, limbs, etc.

A similar principle can be readily adopted by dermatology to emphasize the clinical value of certain parts of the body. The grouping of dermatological lesions of the scalp into one clinical unit is justifiable not only because the scalp is, probably, subject to a greater number of dermatoses than any other part of the body, but also because both diagnosis and treatment of the scalp present peculiar difficulties due to the hairy covering. This anatomical fact of hairy covering readily accounts for the multiplicity of scalp dermatoses and allows us at once to divide these dermatoses into two groups: Diseases of the skin proper and diseases of the hairy appendage.

The difficulties of diagnosis of scalp dermatoses are obvious, since, even in the dry forms, the diseased area is covered and disguised by the mass of hair. In exudative forms these difficulties of recognition greatly increase, as exudative secretions accumulating, drying up, and glueing with the masses of hair, form matted and solid masses of softer or harder consistence. For this reason the first step in making a diagnosis should be the cleaning up of the diseased area by removing crusts and accumulated masses, after softening them with oily solutions, and cutting the hair, if possible.

Eczema.—Among diseases of the skin proper on the scalp, eczema is one of the most common. Yet, in the majority of cases, it does not develop spontaneously and primarily on the scalp, but either spreads on the scalp from the face and neck, or develops secondarily as a complication of some other affection of the scalp, such as pediculosis, impetigo, seborrhea, etc. Thus, in every case of eczema of the scalp, the primary diagnostic consideration should be to determine whether the eczematous condition is of primary or secondary type.

In many cases eczematous features, while having been developed secondarily, so dominate the clinical picture as to disguise and mask the primary affection, such as pediculosis, impetigo, seborrhea, etc. Yet differentiation can be made out, almost in all cases, without particular difficulties, if only we keep in mind the individual clinical characteristics of each dermatosis.

The constant and essential clinical features of eczema without which a positive diagnosis cannot be made are: Eczema has no sites of predilection on any part of the body, and it can occupy any part of the scalp. Eczematous patches have no tendency to assume any definite, regular, or fancy outlines, such as ring-like, circinate, kidney-shaped, etc. Eczematous patches have always ill-defined borders, gradually merging into healthy skin. The only exception to this rule is found in the parasitic types of eczema, which have rather sharply defined outlines. Eczematous lesions, no matter of what type they may be—macular, papular, vesicular, or pustular—never remain discrete, but show a constant tendency to run together into patches. Common eczema never produces ulcers, scars, or loss of hair, and is always associated with intense itching—again with the exception of the parasitic forms, which are the least itchy.

This classical symptom-complex characterizes primary uncomplicated eczema. Should eczema be secondary to some other dermatosis, it will always betray itself by some additional features, uncommon to eczema, or by some modification of cardinal eczematous characteristics.

Thus eczema, following pediculosis, preferably attacks the occipital and temporal regions and follows closely the hairline. Pediculosis eczema is mostly of the pustular variety and presents many scattered patches instead of large diffuse areas spreading in continuity.

Impetiginous eczema of the scalp, *i. e.*, eczema complicated with pus infection, may develop either from a simple eczematous patch, invaded by pus germs, or through eczematous inflammation, engrafting on unrecognized or mistreated impetigo. In spite of a great similarity of these two clinical forms careful examination of the lesions will always enable a clinician to interpret correctly the clinical picture. In the case of eczema complicated with pus infection, there will be presented a diffuse inflammatory area with ill-defined borders, covered with a diffuse purulent exudate or greenish crusts. In the case of impetigo complicated with eczema, there will be found discrete patches with typical impetigo "stuck on" crusts, with inflammatory reaction between and around the patches. Eczema complicating ringworm is particularly common in children, whose tender skin violently reacts to all kinds of irritants. It is the true type of parasitic eczema, and its characteristic features are discrete, sharply defined borders which are usually more active than the central part, slight or no tendency to exudation, and mild itching.

In all these dermatoses of double nature the primary affection is to be treated first, unless the superimposed eczematous inflammation is of hyperacute character, in which case it is to be attended to first.

The treatment of eczema of the scalp is to be conducted on the same general principles as that of eczema of other parts of the body, with one important modification. Should the cutting of the hair be impractical or objectionable, oily or fluid applications should be used in preference to ointments. Should the ointments be used, however, the Lassar paste, which is a most admirable and the most frequently used base elsewhere on the body, is particularly objectionable because of its heaviness and thick coating properties, rendering the cleansing so difficult, and should be replaced by vaseline, lanoline, or lard.

Impetigo.—Impetigo is an extremely common affection of the scalp, mainly in children, and, for this reason, it merits the attention of every practitioner. It may be of the type of impetigo contagiosa, transferred by self-inoculation from the face and hands. In this case the clinical picture will present discrete, sharply defined patches with bulky, "stuck on" crusts, without inflammatory reaction and without itching. The primary impetigo of the scalp is of pustular and follicular type; it may, though, develop secondarily in pediculosis. If not recognized and if treated as eczema with indifferent salves, it may lead to infection of the lymphatics and to deep abscesses. The treatment in the early stages is simple: White precipitate ointment

i.e. mercury ammoniate 5 to 10 per cent. applied after a thorough removal of the crusts acts as a specific; sulphur, 5 to 10 per cent. in lotion, is also good.

Seborrhea.—Seborrhea, i. e., an oily condition, is unquestionably the most important of all diseases of the scalp, not only because it is the most common affection, but because it produces a permanent and extensive alopecia more often than any other disease of the scalp. It is surprising how often it is unrecognized, ignored, and left untreated. Yet by a persistent and rational treatment in the early stages the loss of hair can be stopped, or at least checked and held in abeyance for many years, while in advanced stages it is practically incurable.

Seborrhea is, admittedly, of infectious nature, though the microbe is not specifically isolated. Clinically, seborrhea is manifested in two forms—dry and oily, seborrhea sicca and seborrhea oleosa.

A common condition of furfuraceous exfoliation of dry, grayish white scales—the condition, known to the laity under the name of dandruff—is often regarded as a form of dry seborrhea. This condition—*pityriasis simplex*—is often associated with seborrhea, but, as a clinical entity, it is distinctly separate from seborrhea. Pathologically, pityriasis simplex is simply hyperkeratosis, and its scales are nothing but normal keratinized epithelial cells exfoliating in excess; they have nothing in common with the oily secretion of the sebaceous glands observed in true seborrhea. Bacteriologically, it is due to the spores described by Malassez. Pityriasis should not be left untreated, as it tends to be complicated in time by a true seborrhea with subsequent alopecia. The treatment of pityriasis simplex is similar to that of seborrhea.

The dry form of true seborrhea is characterized clinically by heavy, greasy, yellow scales, adherent to the scalp and hair, and tending to accumulate in crusts. As pointed out by Sabouraud, it commonly develops from pityriasis simplex through a secondary infection with the polymorphous coccus called *Morococcus* of Unna, and growing in characteristic gray colonies; the condition is called *pityriasis steatoides*.

The oily form of seborrhea is manifested by the oily appearance of the scalp, and it is commonly associated with a similar condition of the forehead and nose. If the skin is pinched between the fingers, a number of minute, white wormlike masses can be squeezed out. These greasy accretions are called seborrheic filaments and constitute a characteristic lesion of seborrhea. This condition is often combined with hyperhidrosis. The offending organism is believed to be a microbacillus described by Sabouraud. Occasionally the seborrheic condition sets up an inflammatory reaction of the skin, and thus plain seborrhea is converted into *seborrheic dermatitis*.

The diagnosis of seborrhea presents no difficulty in a typical case. Heavy, greasy, yellowish scales, forming plate-like masses, spreading from the top of the head downward in diffuse, ill-defined areas, are sufficiently characteristic to prevent confusion. *Seborrheic dermatitis* is most likely to give rise to a confusion, as it may closely simulate in appearance eczema, psoriasis, and ringworm. Above all other clinical characteristics should be kept in mind the

tendency of seborrheic dermatitis to spread from the top of the head downward, extending way beyond the hairline on the neck and face and invading with a remarkable constancy the sternal and interscapular regions, and in women the regions between and under the breasts.

From eczema it differs by inducing little or no itching, by a slighter inflammatory reaction, by the absence of papules, vesicles, or pustules, and by the lack of tendency to exudation or infiltration.

From ringworm, besides a characteristic distribution and yellowish, heavy scales, it can be differentiated by the absence of a tendency to clear up in the central part and to be active on the edges, by the absence of hair stumps and patchy alopecia, and by the microscopic test for fungus.

From psoriasis seborrheic dermatitis is differentiated by the absence of the silvery white scales, of sharply defined borders, of intensely inflamed base, and by the difference in sites of predilection. It must be admitted, however, that in some cases it is well nigh impossible to differentiate between psoriasis and seborrheic dermatitis. The fact, that these two affections so often resemble each other and yield to the same group of local applications, is highly significant and points to a closer relationship between them, than it is realized at present.

The treatment of seborrhea is promising only so far as the clearing up of active lesions. We do not know at present of anything that can prevent the recurrences. A permanent cure will, probably, be found along serological lines. The symptomatic treatment consists in washing and cleansing with water and green soap, after a preliminary softening with oil containing 2 per cent. of salicylic acid. Sulphur precipitate, resorcin, betanaphthol 2 to 5 per cent., in watery or alcoholic solutions and oily suspensions are most serviceable. A 5 per cent. ointment of mercury ammoniate is also good. Very efficient is a lotion containing resorcin 1 to 2 per cent., chloral hydrates 5 to 10 per cent., in 10 to 25 per cent. alcoholic solution. It should be kept in mind that resorcin occasionally discolors blond hair green. The acute stage of seborrheic dermatitis is to be tided over with a saturated solution of alum acetate—one tablespoonful in a glass of water or equal parts of lime water and liquid albolene.

Psoriasis.—Psoriasis of the scalp is usually secondary to eruptions on other parts of the body. The diagnosis is made on the presence of the clinical characteristics of psoriasis, which are sharply defined borders, infiltrated, dry, acutely inflamed base, papillary hemorrhages on scratching, silvery white scales (which are pathognomonic, if present), absence of itching, and the history of a chronic course with recurrences. It is to be differentiated from eczema, ringworm, impetigo, syphilis, and seborrheic dermatitis. Differential points have been cited above in the discussion of individual dermatoses. In the treatment of psoriasis, it is well to keep in mind that chrysarobin, our best local remedy in psoriasis, should not be used on the scalp, first, because it may discolor light hair, and, second, because it is very irritating and is apt to set up a violent conjunctivitis. Chrysarobin is usually substituted by mercury ammoniate, salicylic acid, or beta-naphthol.

Syphilis.—Syphilis of the scalp, as a clinical prob-

lem, does not present many difficulties. Syphilides of the scalp are either of secondary nature, as a part of the general eruption in the early stage of the secondary period, in which case the macular and papular types prevail, or it is of primary character, and then it may be limited to the scalp only. A primary syphilide of the scalp is, ordinarily, of the late secondary or tertiary period, and shows a great predilection to assume the pustular, follicular, and gummatous type.

The diagnosis, besides the specific history and possible lesions elsewhere on the body, is made on the presence of general specific cutaneous stigmata, which are a dusky red color, infiltrated base, tendency to form serpiginous or circinate lesions and to ulcerate, producing punched-out ulcers, with scant, gummy secretion drying into greenish crusts, with subsequent formation of soft, thin scars. The differentiation is to be made from impetigo, ringworm, psoriasis, and epithelioma.

Warts.—Some clinical attention should be given to warts on the scalp, not only because, if numerous, they are annoying in the extreme, but also because, due to the constant mechanical irritation, while combing, there is always a latent danger of malignant degeneration. The best method of removing them is by fulguration with the high-frequency current.

Among dermatoses that occur on the scalp, mostly by extension from the face and neck, and only rarely primarily, can be mentioned: Erysipelas, lupus erythematosus, scleroderma, dermatitis exfoliativa, and lichen planus. But because of their comparative rarity they are only of minor interest to a general practitioner, and their consideration will be here omitted.

This completes the review of scalp dermatoses limited to the skin proper. Now we can turn to diseases of the appendages of the skin, viz., the hair follicles and sebaceous glands. There are many, but we will consider only the clinical forms most likely to occur in general practice.

Among diseases of the hair, parasitic forms are most common, and are of great clinical interest. Here belong pediculosis, ringworm, favus, and syco-
sis.

Pediculosis capitis.—Pediculosis of the scalp is so common as to be almost regarded an endemic disease. In the average case it is recognized and successfully treated even by an intelligent layman, who uses crude petroleum mixed with oil as a home remedy. But in the cases, where living parasites or their nits are not in evidence, and in those masked by secondary eczema or impetigo, the diagnosis may be missed even by the physician, if the points of differential diagnosis are not kept in mind. Should the case prove resistant to ordinary treatment, there are a number of other efficient applications available, such as tincture of delphinium, 5 per cent. naphthol in oil, tincture of cocculus indica, equal parts of ether and xylol, bichloride solution, 1/1000, etc. The important detail is to remove all the nits by painstaking combing after a preliminary dissolving of their attachments with diluted acetoic acid. It is essential also that all hats, collars, pillows, brushes, and combs used by the patient should be thoroughly disinfected to prevent a recurrence.

Ringworm of the Scalp.—Ringworm is unquestionably the most often unrecognized and mistreated dermatosis of the scalp and the most frequent cause of alopecia in children. Bacteriologically, ringworm is due to several varieties of trichophyton fungus—small-spored, large spored, etc. Clinically, it is sufficient to recognize four main types: (1) Large discrete patches; (2) small multiple disseminated patches; (3) kerion, the pyogenic type; (4) the alopecia type.

All these clinical forms, however, present certain constant features, pathognomonic of ringworm, which render the diagnosis positive and definite. Ringworm patches are always sharply defined, and always show a tendency to spread at the periphery, so that the central part of the patch, being the oldest in time of development, reaches first the stage of involution and begins to clear up while the edges are the seat of younger and more active lesions. Broken hair stumps are another constant clinical feature of the ringworm. Alopecia, usually, is of the patchy variety, and is only exceptionally complete. The hair becomes dry, lusterless, opaque, brittle, and easily breaks off. Scaling is not excessive, and presents nothing characteristic. An inflammatory reaction is seldom present, and the skin is usually unaltered in color. The prevalent form of ringworm may be due to a certain strain of fungus, and is commonly of pustular type. It reaches its extreme development in the kerion, which simulates perfectly an abscess.

Ringworm of the scalp is to be differentiated from seborrheic dermatitis, psoriasis, favus, squamous eczema, and alopecia areata. The differentiation is made on the points stated above in the discussion of individual dermatoses. The final positive test is the microscopic finding of the trichophyton fungus, after maceration of the hair in 10-30 solution of potassium hydrate, either unstained, or stained with methylene blue.

The treatment of ringworm has been revolutionized with the introduction of x-ray. Epilation by massive measured doses of x-ray is the only radical cure known at present in the chronic stubborn forms. The hair falling after epilation does not return under 2 or 3 months. The treatment should be entrusted only to an expert radiologist. If the x-ray is inaccessible, cleansing with a 2 per cent. salicylic acid in oil, and antiseptic ointments like sulphur 5-10 per cent., or mercury, are serviceable. Also useful are alcoholic solutions of bichloride, 1000; tincture of iodine 10-25 per cent., chrysarobin 2-10 per cent. in ether, benzine or terpentine, betanaphthol 1-3 per cent. in alcohol, and salicylic acid 2-6 per cent. in alcohol.

Favus.—Favus is a rather rare disease in this country, and is mostly imported from abroad. It is extremely characteristic in appearance. It presents discrete or confluent dry patches covered by sulphur-yellow, cuplike crusts, which are perforated by a hair; other characteristic features are asbestos-like dry, grayish masses, a peculiar mousy smell, dry, lusterless hair, and resultant permanent alopecia. Microscopical finding of the fungus is necessary in doubtful cases. Treatment is similar to that of ringworm.

Folliculitis decalvans.—It is rather surprising that syco-
sis—i.e. pus infection of hair follicles, a

condition fairly common on the hairy parts of the face—hardly ever occurs on the scalp in its usual form. It assumes here a modified clinical appearance, and is described under a name of folliculitis decalvans. It differs in clinical appearance from ordinary sycosis mainly by the absence of marked inflammatory reaction and by a predominance of atrophic features—follicular scars slowly leading to patchy alopecia. The disease is very slow in development, and is more resistant to treatment than sycosis.

Alopecia.—Alopecia—i.e., loss of hair—is obviously not a disease by itself, but a mere symptom; yet it is conveniently described as a separate clinical unit because of its great practical importance.

Alopecia can be *congenital*, partial or complete. *Acquired* alopecia presents many clinical types of varying etiology. Their careful differentiation, therefore, is very important, in regard to both prognosis and treatment.

The first type of alopecia, which can be considered physiological, is *senile*, which is commonly associated with other symptoms of partial or general physiological decline, such as hair turning gray, lusterless, and weak. The age of its onset varies in different individuals.

Alopecia prematura idiopathica is due to the defective heredity in this particular line, or to some local affection of the scalp. In many cases this hereditary weakness of the hair is enhanced by other unfavorable factors, such as defective care of the hair, excessive washing, wearing of tight hat bands, continual mental strain, bad air, etc.

Alopecia prematura symptomatica may be due to a number of pathological conditions, the most important of which are of parasitic character, and which present the following clinical types:

Alopecia seborrheica.—It has been mentioned before that seborrhea produces more cases of alopecia than any other disease of the scalp. Alopecia seborrheica is recognized by the presence of yellow, greasy, heavy scales, and by a typical distribution, first on the vertex and then gradually descending, as an ill-defined diffuse area; also by an extremely slow development, with many remissions, and no pathological gross changes in the scalp or the hair.

Parasitic alopecia, due to the fungus of ringworm or favus, will show the above-mentioned clinical characteristics: sharply defined patches with clearing central part and active scaly borders; dull, lusterless, brittle hair; numerous hair stumps in the case of ringworm, and sulphur-yellow, cuplike, mousy-smelling masses in favus.

Syphilitic alopecia in the secondary stage is diffuse, and shows the thinning of the hair all over the scalp, with many small bald patches; so-called *moth-eaten* type of alopecia. Syphilitic alopecia of the tertiary period is of a different character; it presents single or multiple discrete patches of typical specific, scarry tissue—the sequelæ of broken-down and healed-over gummata.

Alopecia due to sycosis or folliculitis decalvans is also of a patchy variety, showing numerous follicular scars.

The last, but not the least, is *alopecia areata*, a fairly common condition in both adults and children. The clinical picture is so characteristic that it should permit no difficulties of recognition. Sin-

gle or multiple patches of oval, round, or variously shaped outline, sharply standing out on the dark background of the surrounding hairy covering, areas of complete and absolute baldness, with perfectly normal skin, unaltered in color or consistence; with no evidence whatever of pathological changes in or around the hair follicles and sebaceous glands; with no scaling, exudation, or crusting of any kind; without itching or any other subjective symptom; with a history of a sudden onset and rapid falling out of the hair in bunches and strands, this symptomocomplex can hardly give rise to a confusion with anything else. In atypical cases, a differentiation is to be made from other types of alopecia on the differential points considered above.

The pathology of alopecia areata is unknown. It is considered by some to be of toxic or trophoneurotic, by others of infectious nature, or a reflex neurosis.

The treatment of alopecia areata consists in the removal and control of the etiological factor, if discoverable. Symptomatically, general tonics and local irritant and stimulating applications, all of which work on the same principle, by producing an active hyperemia of the scalp, increasing the blood supply and thus stimulating the nutrition of the hair. Among numerous applications of this character can be mentioned lotion of tincture of cantharides, tincture of capsicum, tricrosol in 25-50 per cent. solution, chrysarobin in collodion, formalin 20 per cent., lactic acid 30-50 per cent., etc. The best results are obtained by daily stimulation with the high frequency current and massage of the scalp. The prognosis in alopecia generally is good, as the hair returns in most of the cases, though it may take many months for a complete recovery.

Conclusion.—This completes our clinical review of scalp dermatoses. Brief and incomplete as it may be, it clearly shows what a large and important clinical group they form, particularly in children. A differential diagnosis of these dermatoses can be made on definite clinical characteristics and by careful analysis of clinical lesions. The prognosis in this group of diseases is in general favorable, as most of them are very responsive and readily yield to chemical and physiotherapeutic agents.

34 WEST SEVENTH STREET.

STATUS LYMPHATICUS; DEATH FOLLOWING TONSILLECTOMY; AUTOPSY.*

BY WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.

NEW YORK.

ON October 4 there was, among the fourteen cases of adenoids and tonsils to be operated upon that afternoon in my service at Gouverneur Hospital, a little girl five years of age. The child was of a nervous and excitable temperament, and was terribly frightened on being admitted to the hospital. She was poorly nourished, but there was no evidence of any definite organic or constitutional abnormality. No family or previous personal history could be elicited bearing upon the condition from which she succumbed. The tonsils were enlarged and were of the submerged variety. The adenoids were in moderate amount.

At 2.55 P.M. this child was etherized by an expert anesthetist. The tonsils were enucleated by the Sluder method, and the adenoids were removed with the Gott-

*Read before the Society of Alumni of Bellevue Hospital, Nov. 7, 1917.

stein curette. The actual operating time was not over two minutes. There was only moderate bleeding and the patient was removed to the ward in good condition. At 5.55 P.M., three hours after the operation and after the child had recovered from the anesthetic, the nurse noticed that she suddenly became cyanosed. Death ensued before the house surgeon could be summoned. The usual means were employed to revive the patient.

The autopsy was performed by Dr. Schwartz three hours after death. The following were the salient features noted in the report. Thymus gland enlarged, reaching over base of heart and blood vessels; weight 21½ grams. No constriction of the trachea was noted. Heart: foramen ovals open; valves normal. Larynx, trachea, and bronchi normal. No evidences of post-operative hemorrhage. Spleen normal in size. Malpighian corpuscles unusually prominent. Mesenteric glands and solitary lymph follicles of the intestine enlarged. Retroperitoneal glands enormously enlarged, these being the size of hazel nuts. Kidneys normal.

Pathological Diagnosis: Status Lymphaticus.

I am prompted to report this case because of the rarity of the disease, because of the uncertainty which surrounds its pathology, because of its grave significance in operative cases, and because the profession should be constantly reminded that there is such a condition as status lymphaticus, and that it is a menace which must be reckoned with by every operator. It is a danger, too, which, in the present state of our knowledge, cannot be forestalled and guarded against.

These cases are not common. In my own experience, which includes many thousands of adenoid and tonsil operations and a large number of other conditions requiring operation under a general anæsthetic, I have met with only two cases of status lymphaticus, both of which were first identified at autopsy.

According to Bovaird and Nicoll, who weighed and measured the thymus in 495 consecutive autopsies, this gland is 3 cm. wide and weighs 7 gm. in a child one year old. It increases in size for three or four years, and then gradually decreases until puberty is reached, when it either disappears or remains throughout life in a much atrophied condition.

The anatomical relations of the thymus are important. A study of these will indicate at once how an enlarged gland may press upon adjacent vital structures; this is especially true since the thymus lies between two unyielding bony structures, the vertebral column and sternum, the difference between these up to the second year being only 2 cm. The phrenic nerves and the pericardio-phrenic artery are in relation with the thymus on both sides. The lower pole of the gland rests upon the pericardium, reaching usually to the fifth costal cartilage; the posterior surface lying upon the right auricle and ascending aorta and sometimes reaching as far as the bifurcation of the trachea. On the right side it is in contact with the superior vena cava and right innominate vein. The gland has a rich arterial supply, but the veins emerging from it constitute only a single small plexus. This disproportion between the afferent and efferent blood-vessels would seem to favor rapid engorgement of the gland. This has been claimed by some writers to be the cause of sudden death following fits of anger or prolonged crying spells.

The various conditions caused by enlargement of the gland have been stated by Pfaundler to be: (1) Tracheal stenosis; (2) conditions caused by

pressure by the gland upon the circulatory system and nerves; (3) status lymphaticus; (4) laryngo-spasm; (5) discrasies caused by functional disturbances of the gland itself.

Only two views have received wide acceptance: (1) That there is a neurosis of some sort, toxic or otherwise, and that death is a cardiac death; (2) that there is compression of the trachea and that death is due to strangulation.

Apparently the case which I report to-night was a cardiac death. These are the cases that give no warning, and the only evidence is revealed at the autopsy.

In operative cases death may occur during the administration of the anesthetic, two or three hours, or as long as twenty-four hours after the operation. In my opinion the anesthetic and not the operation is usually the important factor in determining the fatal issue in thymus cases.

In regard to compression of the trachea and death by strangulation: These cases, as a rule, give a history of gradually increasing dyspnea extending over a period of weeks or months. In 1904, Jackson reported the case of a child 4 years of age in which the compression was demonstrated by the aid of the bronchoscope. The dyspnea was relieved by using a long tracheotomy tube and cure was later effected by removing the thymus.

There have also been reported a number of cases of impending strangulation that have been relieved by the surgical removal of a portion of the gland, or by pulling the gland forward and stitching it to the sternum.

One case is reported as having been relieved by x-ray treatment.

In 1904 I reported before this society a case of thymic tracheostenosis. The patient, a baby five weeks old, was brought to the hospital suffering from extreme dyspnea. This condition had existed from birth and had been getting much worse. Tracheotomy and the introduction of a long tube relieved the dyspnea, but the child died later from bronchopneumonia.

There is at present, so far as I know, no certain means for diagnosing this condition in children. Probably the x-ray is best, but its evidence is fallacious, and at best can scarcely be considered more than corroborative.

A closer study and a more intimate knowledge of the internal secretion of the thymus gland may suggest some test either of the blood or the secretions which will enable us to unravel the mystery which now surrounds the pathology of this gland.

69 WEST FIFTIETH STREET.

Therapeutics of Epidemic Icterus.—Foà in the belief that this affection is due to a protozoan has used quinine, methylene blue, arsenicals and mercurials without the slightest effect on the course of the disease with the possible exception of calomel.—*Giornale della R. Accademia di Torino*.

Acute Dropsical Fatal Beriberi.—Fiessinger and Leroy saw a case of dropsical beriberi in a negro end fatally in 10 days, with cardiac arrhythmia and acute suprarenal syndrome (lumbar and epigastric pains, hypotension, etc.). The postmortem examination showed degeneration of the heart, liver kidneys, and adrenals.—*La Presse Médicale*.

Military Medicine.

THE NECESSITY FOR SURGICAL INTERFERENCE IN WOUNDS OF THE HEAD FROM PROJECTILES.

DURING the first year of the war, in which cranial surgery underwent a sudden evolution, a number of statistics were published showing that the immediate results of craniocerebral surgery in serious cases are very encouraging, while the remote results are better than some pessimistic statistics might lead one to believe. So far as cerebral lesions are concerned, a mean figure of 60 per cent. of successful outcomes from trephining may be at present admitted. Lapointe concludes that if these cases were not operated on, given the complications which inevitably occur and which can be avoided only by trephining, the mortality would reach 90 per cent. In these cases of extensive cranial lesions with large perforations, it is unquestionably the proper practice to operate at the ambulances at the front, because early operation offers the only hope of saving the patient. The evacuation of these patients should be delayed as long as possible, because the trip to a base hospital is always badly borne by them.

Considering now trephining for cranial traumatism without cerebral lesions, the mortality given by Lapointe is 7 per cent. Tixier's statistics give about 6 per cent. mortality (35 operations with 2 deaths). Even should these figures be above the actual percentage, on account of remote complications which may arise, it is quite certain that 10 per cent. would be the utmost limit. Therefore, it is the surgeon's duty to trephine in these cases, because when left untreated the mortality at once reaches from 35 to 40 per cent.

In minor cranial wounds, those that must be sought for in order to be detected, the urgency for operating is less absolute perhaps, and it will probably be better practice, when the number of wounded coming in is very great, to evacuate such head cases to the rear, but only on the condition that they can be properly operated on if necessary and followed for a long time.

The evacuation of cases of head injury must not be done lightheartedly, because the occurrence of infectious phenomena not infrequently follows the change to another ambulance or base hospital. The ideal would be for the surgeon who trephined to be able to follow the case for at least some weeks. At all events wounds of the skull should be operated on in a front ambulance; the recovery of these patients is a question of hours and miles and great attention must be given to very small wounds of the scalp which often conceal serious lesions of the skull or brain.

In a very interesting work (Thesis, Lyons, Nov., 1915), Fromant comes to the following, and we think, logical conclusions in the case of head injuries: Every head wound from projectiles should be treated by incision of the scalp under local or general anesthesia, as incision alone can give a clue to a lesion of the skull, and when this is found, even if it is minute, trephining should be systematically practised. The operation should also be done in cases where the general symptoms denote

a cerebral lesion although no lesion of the skull may have been discovered. Trephining is necessary to avoid immediate disaster and to avoid the development of secondary accidents, particularly infection with its high mortality, and the possible occurrence of epilepsy some months after receipt of the injury. From the military viewpoint, trephining should be resorted to because the men who have been trephined can return to the front sooner than those who have not, and if the operation is not done immediately after the receipt of the injury the patients remain inapt to return to duty for a long time.

The First Symptoms of Poisoning by the New "Mustard" Gas.—The subject of gas poisoning is still very complex and poorly analyzed. Within a few months a new shell gas has been used by the Teutons, and, owing to imperfect ideas of its chemical characters, it is known as mustard gas. Giraud has written an account of this substance for the *Journal de Médecine et de chirurgie pratiques* for November 25. Recently he has had the opportunity of rendering first aid to numerous victims of this weapon. The bombardment with these shells occurred at night. Exceptionally the shells were seen to explode by daylight, and send up a narrow column of smoke. Attempts were made to gas the reserve troops, the first lines being intentionally spared. The shells whistle in their passage, and the noise of explosion is feeble. The mustard odor is rather faint, and if a soldier's attention is absorbed he may not get it.

The symptoms produced by the gas are delayed; there are no immediate effects. They are of three types: ocular, respiratory, and cutaneous. The first named are the first to appear; they are perceptible in from 6 to 12 hours, and fully established at the end of 24 to 48 hours. While some severe burns are apparent very early—even almost immediately—as a rule they do not become evident until from 4 to 15 days. These late burns are always mild. Finally, respiratory symptoms appear in from 2 to 4 days. The ocular symptoms occur most and the burns least frequently. The ocular symptoms of mustard gas were described in the *MEDICAL RECORD* of December 22. The respiratory symptoms are most pronounced in the larynx, and next in the trachea and large bronchi. Aphonia first results, is total, and lasts 3 or 4 days. It is at this juncture that the trachea and large bronchi become involved. A pseudo whooping cough sets in, followed after 2 or 3 days by abundant expectoration. Dyspnea becomes marked, and the victim cannot lie down; no matter how fatigued, he must sit or stand in order to breathe. The respiratory disorders are tenacious. After a week there is a tendency to improve, but any unfavorable circumstance may cause a relapse. Two or three relapses are not uncommon.

The burns were mentioned at some length in the earlier notice, especially in reference to moisture. The early burn consists of a large plaque of erythema upon which may appear blisters or only vesicles. Upon a hairy surface pus forms. These lesions may so resemble ordinary sunburn as to deceive completely the victim; naturally this is seen only on exposed localities. But the burns occur by locality in the most arbitrary fashion, the penis and

scrotum, about the joints (knee, ankle), the thighs, buttocks, neck, and back in the order named. The exposed parts are rarely affected, hence the confusion with sunbeam.

The treatment is very simple—sodium carbonate in 3 per cent. solution for ocular lesions and burns. Nothing avails much for the respiratory symptoms, although symptomatic treatment should be given.

Provision for the Care of War Neuroses and Psychoses in France.—Professor Boschi, director of a neurological military hospital in Italy, gives a brief account of a trip to France undertaken in the interest of his special work (*Giornale de Medicina Militare*, November 30). Paris, because of both its resources and its proximity to the fighting line, was naturally the place of destination. The services at both the Salpêtrière and the Pitié are largely devoted to military activities and there are military divisions in the insane asylums or rather connected with them. Near the Villejuif is a neurological center rich in appliances for physiotherapy which was organized by Souques and is directed by Thomas. At the Grand Palais in Paris is a great service for reeducation. In the Hôtel des Invalides a similar service is under way with the especial aim of reeducating maimed soldiers for agriculture, and there is also a service for teaching certain trades.

The author, however, was chiefly interested in the psychoneuroses, and learned that small neurological services are scattered throughout France and that specialism is the rule. Thus Professor Roussy has a service in the provinces limited to traumatic hysteria, the treatment consisting chiefly of psychotherapy, suggestion being conveyed under many forms. In three months' time over 200 subjects have been discharged cured. This institution (at Salino) will doubtless serve as a model for others. Another well-known service is that of Vincent at Tours. Naturally the great cities have their services for psychoneuroses. There is one at Val de Grace, while Laignel-Lavastine conducts another at the Maison Blanche. At Lyons Sollier conducts a neurological center in which psychotherapy is carried out incidentally, in connection with reeducation. The latter term is of course applicable to disordered mental functions. Physiotherapy, education, and psychotherapy represent three methods for attaining a common result. A striking feature at Lyons is the special service for surgery of the nervous system under Villandre. Much work is done in cranioplasty, especially for the closure of fistulæ, with the best results; doubtless many cases of late sepsis are prevented.

The author attended the conference for Professional Reeducation in May last, which was international in origin and membership. Neuropsychic victims were placed under "blind, deaf, etc.," which did not impress the author as very flattering. However, he found under one section provision for those incapacitated by severe nervous injuries. He was the only Italian present. So-called reflex disorders played a great rôle in this material, although at first sight the chief motivation would seem to be psychogenic. Both factors are well represented and both have to be considered

in treatment which includes reeducation and physiotherapy with their added psychotherapeutic possibilities. Apparently indirect suggestion is chiefly practised in all services. Nowhere do we find any special reference to hypnotism or psychoanalysis. Moral reeducation is perhaps the nearest approach to pure psychotherapy, and this does not seem to be carried out alone. The author makes no special allusion to victims of pure psychic shock or commotion and such affections as he mentions have a material organic sub-stratum.

Gunshot Wounds of the Kidney and Ureter.—Colonel Andrew Fullerton, writing in the *British Journal of Surgery* for October, 1917, says that the signs and symptoms of injured kidney are as follows: Hematuria, which may be microscopic, moderate, or profuse. It is well in a doubtful case to ascertain that the blood is not coming from the bladder, as is so frequent in associated injuries to the spine with hemorrhagic cystitis. Fullerton has seen splashes of hemorrhage scattered over the bladder wall in a case in which a piece of shell had injured one of the lumbar vertebrae without involving the cord; until eptoscopy had revealed hemorrhage in the mucous membrane of the bladder, the case was thought to be one of injury to the kidney or ureter. It is also well to bear in mind the possibility of hemorrhagic cystitis unassociated with spinal injury, as he has seen several examples in unwounded men coming down from the front. Other causes of hematuria independent of injury, will suggest themselves to the surgeon.

In addition to these special signs indicating renal or ureteric injury, the following are often present: Shock is frequently met with, and may be due to accompanying injury of the abdominal viscera, thorax, or spine. Anemia after profuse loss of blood, is often very marked in a patient when he reaches the clearing station or the base. Vomiting was reported in about 25 per cent. of the cases. It may have been more frequent. It occurs in uncomplicated cases, but is much more likely to be present when the abdominal viscera have also been injured. Tenderness and rigidity of the abdominal wall are present in most but not all of the cases. These symptoms may be due to injury of the peritoneum, injury to the abdominal viscera, injury to the pleura and diaphragm, blood in the peritoneal cavity, or retroperitoneal hematoma. In some of the reports sent down with the patients from the clearing stations, the definite statement has been made that on arrival there tenderness and rigidity have been absent. Abdominal distension is frequently met with, as might be expected. In those cases associated with spinal injury it is very likely to be present. Dullness in the flanks has occasionally been seen. A tumor in the flank, due to the perineal extravasation of blood, is sometimes palpable. This may be a sign of importance in certain transverse wounds in which it is not easy to locate the kidney affected. Fever may be present, and is due to the fact that many of the wounds are septic.

Defense Against Venereal Infection.—In the November issue of *Public Health*, the journal of the Michigan State Board of Health, is published a paper by Dr. Aldred Scott Warthin regarding

venereal diseases in the State of Michigan, in which he says that of all the weapons of defense against venereal infection the most important is education. At a recent meeting in Washington this idea was emphasized over and over again; but we were told by the Subcommittee on Venereal Prophylaxis of the Council of National Defense that the Government had no money for educational work of this kind in the cantonments. The plan outlined for the Michigan Board of Health is already proving a practical one in the Western Department of the Army. During the five weeks ending September 22, 1917, there were 290 cases of venereal infection reported, and the source of the infection was ascertained in 134 cases. In one city alone 30 clandestine prostitutes are now securely confined in a hospital ward, under treatment, and are no longer a source of infection. Through army regulations the infected soldier is automatically quarantined for treatment, and he should be kept in quarantine until he is no longer regarded as dangerous. The man or woman infected with venereal disease is a menace to the community; if he or she transmit it in the usual way that individual is guilty of a crime against the health of the public and against future generations. An infected prostitute who pursues her calling and communicates disease to her patrons is guilty of a still greater crime, and if her patrons are soldiers this crime becomes even more serious in that it aids the enemy by reducing the efficiency and numbers of our fighting force. Why, says Dr. Warthin, should this dangerous class be tolerated any longer? In this military emergency we may take a long stride forward by putting the case of venereal disease where it belongs, in the front rank of diseases dangerous to the public health. It affords a wonderful opportunity to advance the cause of civilization and to protect the health of the nation. In this attempt it is the duty of every intelligent citizen of the State to stand behind the health authorities and give earnest support to their efforts to overcome these plagues.

Orthopedic Surgery in War Hospitals.—Of course, orthopedic surgery has made great strides since the beginning of the war. Recruits have been treated for deformities, congenital and acquired, and wounded soldiers for deformities and disabilities of the locomotor apparatus. In Pott's disease, as Vincent Moxey points out in the *Practitioner* for November, 1917, attempts are being made to shorten the period of recumbency by means of the autogenous bone-grafting operation of Albee and the local osteoplastic procedure of Hibb, the object being to set up an osteogenesis about the arches of the affected sequent, and produce a synostosis of the laminæ and spinous processes of the contiguous vertebræ. Albee's method is to transplant a graft from the patient's tibia into a cleft made by splitting the spinous process. Hibb does not use a graft, but sets free osteoblasts by splitting the spines transversely, fracturing them up and down and interlocking them with the spines, similarly treated, of the adjacent vertebræ. Autopsy has shown that the object aimed at may be attained. The period of recumbency can be very much shortened, possibly this may be overdone.

As to the risks, it is obvious that such a procedure as Albee's calls for a very high surgical technique. Apart from the risk incidental to any such operation, Moxey draws attention to the fact that there is a special danger in handling cases of fractured spine under an anesthetic. Further, there is considerable danger of dissemination of tubercle; children under five, in Moxey's opinion, should certainly not be operated upon. Whether the ultimate results are better than those obtained by older and safer methods is doubtful. In fracture of the spine in workmen, Brackett holds that splinting by means of bone-graft, after the immediate symptoms are over, is the rational procedure. Finally, Finkelstein relieved a case of spondylitis deformans by means of Albee's operation.

Public Health Service Remedies Physical Defects.—Secretary McAdoo recently approved an order directing the officers of the public health service to communicate with the chairmen of examining boards for the purpose of furnishing advice to all men rejected on account of curable conditions, and to request them to direct such persons to apply to the officer of the Public Health Service in order that he may assist them to improve their physical condition so as to be fitted for military service. A report recently received from the medical officer in charge of the Marine Hospital at Detroit, Mich., shows that this order is having results and that already a number of men in that vicinity who were at first rejected on account of physical defects have had such defects remedied and have been accepted for military service.

The Army Mortality.—A summary of health conditions in the National Army for the week ended December 21 shows that deaths from disease number 118, against 97 the week before. In the National Guard the deaths numbered 120, against 165 for the week before. In the National Guard the deaths from pneumonia numbered 77, in the National Army 87. The non-effective rate for the entire National Guard for the week was 47.8 per thousand, against 48.6 for the preceding week. The admission rate for disease was 31.1 per thousand, against 32.6 for the preceding week. The non-effective rate for the National Army was 41.8 per thousand, against 40.4; the admission rate for disease was 34.3 against 34.7. Between September 21 and December 14 there have been 1391 deaths in the armies now in the continental United States. This includes men in the Regular Army, the National Army, and the National Guard Army, but does not include deaths in the Expeditionary Forces. During this period there were 144 deaths in the Regular Army, which had an average strength of 202,009 men in the United States; 494 deaths in the National Army, which had an average strength of 387,233 men, and 753 deaths in the National Guard Army, which had an average strength of 327,480 men in the United States.

Red Cross to Act for Army.—Army orders issued from Headquarters in Washington have designated the American Red Cross as the distributing agency of the Quartermaster's supplies

sent "to American soldiers and others who may be prisoners in the hands of any power with which the United States may at any time be at war." The Red Cross has already established at Berne, Switzerland, machinery through which food and clothing have been forwarded to Americans held prisoner in Germany and so is prepared to carry on this work for the War Department. No announcement has been made from the navy, but it assumed that the order includes naval prisoners. The order provides that no money may be sent to prisoners for the purchase of food.

Red Cross Bandages Poisoned.—A report has leaked out that 3400 surgical bandages rolled by the women of Toledo have been poisoned while in transit from Toledo to Cleveland. The bandages were destroyed at the headquarters of the Lake Division of the Red Cross. Agents of the Department of Justice are hunting the conspirators.

American Medical Officers and Nurses Commended.—Field Marshal Haig has submitted a list of persons serving on the western front as deserving special mention. The list has been published in the London Gazette and includes the following: United States Hospital Units—Lieut.-Col. H. Cabot, Harvard; Lieut.-Col. C. C. Collins, Chicago; Major G. W. Oride, Lakeside; Major H. Cushing, Harvard; Lieut.-Col. M. Delaney, Philadelphia; Lieut.-Col. J. D. Fife, St. Louis; Lieut.-Col. H. L. Gilchrist, Lakeside; Major L. L. Hopwood, Presbyterian; Major V. H. Kazanjian, Harvard; Lieut.-Col. R. U. Patterson, Harvard. United States Medical Reserve Corps—Private A. Mason, Harvard.

Nurses—Miss B. M. Alexander, Chicago unit; Miss S. Briggs, Lakeside unit, Cleveland; Mrs. J. Christie, Presbyterian Hospital unit, New York; Miss C. Cuppidge, St. Louis unit; Miss M. Dunlop, University of Pennsylvania unit, Philadelphia; Miss G. M. Gerrard, Harvard University unit; Miss C. Hall, Harvard unit; Miss H. G. McClelland, Philadelphia unit; Miss I. McKee, Lakeside unit; Miss L. Marsh, Presbyterian Hospital unit; Miss J. C. Stenson, St. Louis, and Miss D. Arch of the Chicago unit. American Nursing Service—Sisters V. Allen, Harvard; G. Allison, Lakeside; M. Clinch, Harvard; G. Davidson, Harvard.

Another Appeal for Nurses.—An announcement from the War Department, on December 29, states that the present strength of the Army Nurse Corps is 3800, while 37,500 nurses will be needed on the basis of present estimates for an army of 1,500,000 men. The present rate of enrollment does not meet these demands. The hospitals at National Guard and National Army camps still need 371 nurses to bring their quotas up to the minimum of 65, considered necessary for each. In order to enroll the needed number some requirements are being waived.

Christmas Red Cross Drive a Success.—The Membership Committee of the American Red Cross announced on December 29 that the Christmas drive had resulted in enrollment of 20,000,000 members; of this number 15,000,000 are new members. The Washington Headquarters announces that every one of the thirteen national divisions has exceeded its estimated quota.

Serbia Thanks Red Cross.—The Serbian War

Mission made an official visit to the National Headquarters of the Red Cross recently for the purpose of thanking that organization for the relief work done in Serbia since the beginning of the war. The work of Dr. Edward W. Ryan, who for a year directed the Red Cross Hospital at Belgrade and remained at his post after the invasion of Serbia by the Austro-German troops, and that of Dr. Richard Strong's commission in relieving the typhus fever epidemic of three years ago, were especially commended.

Antivivisection Federation and Red Cross.—The National Antivivisection Federation, which recently announced its intention of bringing proceedings to enjoin the Red Cross from devoting \$100,000 of its funds to vivisection experimentation in army hospitals in France has issued a statement calling upon James Jackson of the New England Red Cross to prove that the proposed vivisection in France was first suggested by medical officers attached to General Pershing's staff and also to prove that this action against the Red Cross is part of a pro-German propaganda. Mrs. Belais, the representative of the anti-vivisectionists, claims that the proposal to devote Red Cross money to vivisection work was first made by American surgeons, and that while all of these men are engaged in hospital work in France none of them is an army officer or under the authority of General Pershing. She also seems to think that her action in opposing measures designed to save the lives of American soldiers is not a practical form of German propaganda.

A Medical Unit for Palestine.—Among the plans of the Zionists for the rehabilitation of the Holy Land is included the sending of a strong and well equipped medical unit to grapple with the medical and sanitary problems in that land in which scarcely any physicians remain.

First Lieut. H. C. Boyle of the U. S. Medical Officers Reserve Corps, attached to the British forces, was severely wounded in action on December 7, according to a report sent to the War Department by General Pershing.

Christian Scientists Accused of Unfriendliness to the Red Cross.—According to a report in the New York Times an unpleasant feature of the Red Cross drive week occurred at Aeolian Hall, where permission had been given for the placing of a booth in the lobby. Wednesday night a Christian Science gathering is held in the hall. When the vanguard of Scientists appeared they tore down the Red Cross posters and destroyed the booth, telling the booth chairman, a woman, that under no circumstances could she solicit membership there, and saying that Christian Scientists were not in sympathy with the Red Cross movement.

Retired Naval Surgeons Recalled to Active Service.—The *Official Bulletin* states that 493 retired naval officers have been recalled to active service, and among them are 27 members of the medical corps—1 surgeon general, 6 medical directors, 3 medical inspectors, 8 surgeons, 5 passed assistant surgeons, and 4 assistant surgeons. One hundred and thirty-eight officers who had resigned from the Navy have returned for the duration of the war and are now officers of the Fleet Naval Reserve. Among these are 3 passed assistant surgeons and 2 assistant surgeons.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

SEPSIS AND ANTISEPSIS.

BEFORE the war, antiseptics had fallen somewhat into disrepute. That is to say, under ordinary conditions, in hospitals, at any rate, asepsis could be attained almost without the aid of antiseptics. Of course, it was quickly found that in war asepsis could not be obtained by methods similar to those practised in times of peace, and antiseptics and other means of combating sepsis were initiated and developed. Even now there is no unanimity of opinion with regard to the most effective mode of rendering wounds free from hurtful germs, although certain antiseptics seem to have proved themselves both potent as germicides and practically harmless to healthy tissue.

In the *Annals of Surgery* for November, 1917, Dr. Frank Fowler contributes a paper on the valuation of asepsis and antiseptics, and summarizes various conflicting opinions as follows: Whiting and Slocum state that alcohol, 40 to 95 per cent., will kill the *Bacillus typhosus* in practically the same time as various coal-tar derivatives in alcoholic solutions of from 60 to 65 per cent. Nevertheless, they consider the phenols to be more efficient germicides. Post and Nicoll learned that mercuric chloride has very little germicidal action in aqueous solutions. Whiting believes that alcoholic solutions of mercuric chloride are much more efficient, especially on dry skin.

Grossich emphasizes the importance of using alcoholic solutions of iodine on dry skin. Whiting says of alcohol: "As a solvent, or vehicle for the various antiseptics used on the skin, it is vastly superior to water, the alcoholic solutions penetrating more deeply and having greater germicidal power than the aqueous. Kelty and Packer conclude that alcohol is practically inactive as a germicide. Post and Nicoll rank alcohol, in solutions of more than 10 per cent., as one of the most active germicides. Fowler himself thinks that some investigators have underestimated the germicidal power of alcohol. Bovee's tests of the skin, leaving the iodine on, gave negative cultures fifteen days after the operation. Robb believes that the action of iodine is merely inhibitory, and he fears peritoneal invasion by unkilld germs during operation. Robb

and Whiting both obtained sterile cultures before neutralization of the antiseptics, but a large percentage of growths occurred after neutralization. Post and Nicoll also consider tests of doubtful value unless the action of the antiseptic is stopped forthwith. Fowler, commenting on iodine as a skin disinfectant, says that if iodine is allowed to remain upon the skin it penetrates into the deeper layers, and there are no means of determining how long its activity may continue. The consensus of opinion classes iodine as an effective germicide. Granting that its action may be delayed, or that perfect asepsis of the skin is unattainable, or assuming, with Robb, that iodine merely inhibits germ life, nevertheless the tissues, including the peritoneum, can defend themselves against limited numbers of bacteria.

Morris has enumerated the disadvantages of rubber gloves, but Fowler holds that the fact that hand sterilization is so difficult and glove sterilization so easy would seem to outweigh the objections to the use of the latter. Seeling and Gould are convinced that laboratory tests which do not simulate clinical conditions are of little value; that alcohol in solutions of 50 per cent. or more is strongly germicidal, but less so than iodine; that a solution of alcohol and iodine together is stronger than either alone; that alcohol, carbolic acid, and iodine can penetrate animal membranes, and that penetration is facilitated by the presence of oil in the skin. Lambert has shown that iodine alone of various tested antiseptics will kill bacteria rather than tissue cells.

The salient facts of Fowler's analysis of the opinions of various surgeons regarding the value of antiseptics are as follows: (1) Abundant clinical evidence of the efficacy of iodine in skin sterilization has been corroborated by laboratory findings. (2) The germicidal action of mercuric chloride is too slow to be of value in sterilization of the skin. (3) Eternal vigilance is the price of asepsis.

THE PROGNOSIS OF POST-ECLAMPTIC PSYCHOSES.

IN the opinion of the majority of writers, the prognosis of post-eclamptic psychoses is very favorable, although there are a few of the contrary opinion. This would naturally be so, given the importance of the question. Jaisson is even of the opinion that the mental disturbances following eclampsia may terminate in dementia. In certain patients who are weakened by some former affection presenting an excessive debility, this may occasionally occur, but with this exception the psychosis tends toward a rapid recovery. The mental disturbance remains stationary for some days and then periods of calm appear, during which the patient renews contact with the outer world, consciousness returns, and the family and surroundings are recognized. These lapses into a normal mental state become more and more frequent until complete recovery results.

In other still more fortunate instances the psychic changes last hardly more than a few hours, and either instantaneously or upon awakening from a natural sleep or deep coma, a complete return to reason takes place. Such instances are not common, though, generally speaking, the disturbances of the intelligence do not last more than some days or weeks. Some cases may be prolonged for several months although the affection is recovered from in less than a year, this occurring either suddenly or progressively.

As has been pointed out, recovery takes place in most cases within one or several weeks, but in some series of cases, particularly those published by Olshausen and Lallier, the pathological periods were much longer, covering as much as seven or eight months, or else the subject died during the early weeks of the mental process. Such facts render the prognosis less good, but in the prolonged cases the mental disturbances partially disappeared and at length a cure was obtained. When death occurs it is due to some intercurrent process, such as bronchopneumonia or dysentery, or to an abnormal duration or an extraordinary intensity of the eclamptic paroxysms. If still further proof of rapid recovery from post-eclamptic psychoses is demanded, it is sufficient to consult the records of various insane hospitals. The figures offered by these institutions show that there are very few cases of commitment following puerperal eclampsia. Those patients who are admitted under this heading remain for only a short time and leave in an absolutely normal moral and psychic state.

It cannot be denied, since cases are there to prove it, that the mental process may become incurable and end in dementia, but they are few in number and furnish the exceptions that prove the rule.

A WINTER EPIDEMIC OF POLIOMYELITIS.

POLIOMYELITIS in epidemic form is popularly supposed to be essentially a hot-weather disease. This, however, is by no means borne out by facts. A recent winter outbreak of the disease in Elkins has drawn particular attention to the relation between weather conditions and infection.

In *Public Health Reports* for November 30, 1917, Dr. J. P. Leake discusses the question of winter epidemics, and shows from a study of the official meteorological records—Norwegian, Swedish, Austrian, Prussian, Hessian, and American, that several of the outbreaks occurred when the thermometer was nearly constantly below the freezing point, in some cases even below zero Fahrenheit. Many of the conditions at Elkins and in other localities in which winter epidemics have occurred were such as to discredit most of the theories regarding the etiology of the disease. Dust, for example, was absent, there were no unusual prevalence of caryza among the general population, no biting flies were in evidence, the instrumentality of bedbugs and lice could be excluded, and neither domestic animals nor ingested material could be incriminated as causing

the poliomyelitis at Elkins. On the other hand, evidence of direct contact was lacking in 74 per cent. and the writer's assertion that in such cases the disease must have been communicated by carriers or unrecognized cases is not entirely convincing.

The following are Dr. Leake's conclusions, based upon the results of his study of this epidemic: "(1) Modes of spread other than by human contact are improbable. Persons and not things should receive our attention. (2) Even including all the nonparalytic cases which we could recognize, direct contact with the cases themselves is responsible for only one-quarter of the incidence. (3) As passive carriers adults are probably more important than children. (4) There are probably many unrecognized cases of the disease during an epidemic of poliomyelitis, about as numerous as the paralytic or the recognizable nonparalytic cases, and such cases are likely to have symptoms referable in the first instance to the digestive tract. (5) Quarantine of the case for two or three weeks is long enough; but another member of the family is just as likely to be dangerous as the patient, and general intermingling, particularly contact with children, should be prevented."

EXPERIMENTAL STUDIES ON TYPHOID CARRIERS.

WE have no certain means of freeing germ carriers from their germs. The carrier problem is largely bound up with typhoid fever, and a rational campaign naturally begins with animal experiments in which Eberth's bacillus is used. It has been claimed that when a culture of the latter is injected into animal veins the bacilli may be found in the gall-bladder for about one week in some 70 per cent. of injected animals. After this period, however, they occur so infrequently, or to such a small extent, that there is little likelihood of making animals carriers by this method. Others have succeeded in injecting cultures directly into the gall-bladder, and in this way "six-months carriers" may be established at will among rabbits. But during this period it is impossible to free animals from the bacilli, nor do attempts at prophylactic immunization prevent the animal from becoming a carrier. The experiment conditions are also highly artificial, for before making the injection a ligature is passed around the gall-bladder to isolate the fundus, and this practice naturally damages the viscus.

Venema, in an article in the *Berliner klinische Wochenschrift*, No. 34, 1917, relates some experiments in which ligation of the gall-bladder was omitted. The technique was very difficult, but cultures were successfully introduced with a minimum of injury. A study of the feces showed that but few bacilli escaped by this route. In the majority the stools remained sterile throughout, with the presumption that the microorganisms were colonized in the gall-bladder. The animals were killed at regular intervals, from 7 weeks to 9 months after the injection. In no case did illness of any

kind develop. The gall-bladder seemed normal to the naked eye. From the bile cultures could invariably be prepared. There is considerable evidence that the presence of bacilli in the bile affected the nature of the latter, and in particular favored the formation of concretions.

The author next proposed to inject immune serum into the venous system of the animals before inoculation of the gall-bladder. In three animals thus tested the animals became carriers, even better carriers than before. This perhaps is in accordance with the fact that human carriers are immune to autoinfection, and is evidence that prophylactic immunization will not prevent the individual from becoming a carrier.

FAT EMBOLISM IN FRACTURES.

EMBOLISM of various organs and thrombosis of bloodvessels have long been understood to be among the serious untoward complications of surgical operations, not easily anticipated and often the cause of sudden death. The same serious results may follow fractures, usually of the long bones. The embolism by fat globules after fracture may affect the brain, lungs, kidneys, liver, and other organs. Not all cases of fat embolism give symptoms or are fatal. There are many instances where fat is found in the blood without symptoms or the slightest suspicion of the condition. Indeed, the amount of fat in the blood is no indication of the severity of the attack. In effective cases of fat embolism, shortly after the fracture of a long bone like the femur, there are delirium, sometimes very violent, coma, dyspnea, high and irregular pulse rate, and often collapse symptoms. The mortality of cases with symptoms is very high. Not only is fat embolism a possible occurrence after fractures but it is one of the conditions to be borne in mind in operative bone surgery. The symptoms of fat embolism may not manifest themselves until after surgical interference, and it may be a medicolegal question whether the condition is due to the fracture or to the operation. Because of the delirium, coma, or symptoms referable to the other organs affected, the diagnosis of fat embolism is not often made, but a diagnosis of a pathological condition peculiar to those organs may be made. The presence of delirium and coma, the delirium being at times so violent as to require restraint, has often led to an erroneous diagnosis of delirium tremens, especially when these fractures are received during an alcoholic debauch or in a chronic alcoholic subject. This may figure very largely in the medicolegal controversy following such an injury. A closer observation of fractures, especially of the long bones, with these points in view, with blood examination for fat globules, will probably bring to light a great many more cases of fat embolism, and will serve to differentiate the condition from delirium tremens or other conditions sometimes mistaken for fat embolism.

THE EXPLOSIVE PENCIL.

REPORTS have occasionally appeared in the daily press of the mutilation of Belgian boys to prevent them from taking up arms in future wars against

Germany. These mutilations have been said to consist of amputations of the right hand, but details have usually been lacking. An article in *Le Caducée* for November 15 throws some light on the manner in which such mutilations may be effected, by making the victim contribute to his disaster. A boy of 14 in the conquered area of France was first offered cigarettes by a German soldier. These were longer and firmer than the ordinary cigarette, and the boy declined them. The soldier then offered him a violet pencil the point of which was protected by a copper cap. The boy sharpened the unprotected end and made some marks, but the crayon soon ceased to mark, and he then for the first time used the fingers of his right hand to remove the cap. Instantly there was an explosion, and the index, medius, and thumb were blown off entirely, while the ring finger hung by a shred of flesh. He was taken to the local German hospital, where he remained 8 days. He accused and identified the soldier, who did not deny his guilt. The German clergyman warned the boy, on his discharge, not to mention the explosive pencil. It was learned that the cigarettes offered to the boys were also explosive, and that one lad had had his face burned upon lighting one. A boy of 8 had also picked up an explosive pencil, which cost him four of his fingers. In addition to these three actual victims a man who was offered one of the pencils refused it, and doubtless saved his hand. The supposition was that some laboratory man in a munitions factory had contrived these pencils and cigarettes, for what immediate or remote purpose can only be surmised. Whether the child was to be the special sacrifice does not appear, while the circumstances would make it certain that no considerable number of victims could be expected, because the public would soon be on its guard. We can only suppose that such a form of activity was exhibited for advertising purposes—for the publicity of one of the myriad expressions of German frightfulness which must be dangled before the enemy constantly lest he forget. The German mind calculates on the action, but never realizes that there will be a full reaction to such violence, or, if it does, it thinks that with the assured support of the kaiser's junior partner "dort oben," it can safely ignore it. Some day it will recognize the power of the "blood of the martyrs."

A CASE OF CONGENITAL ANORCHIA.

ACTUAL anorchia as distinguished from cryptorchia is such a rare condition that but six cases are on record and none since 1860. The seventh case has just been reported by Wildbolz (*Correspondenz-Blatt für Schweizer Aerzte*, September 29). The case is of especial interest as the first to be studied since the creation of endocrinology as a science. The teaching at present is that failure of the testicle to develop fully is to be attributed to insufficiency of the thyroid or some other gland of internal secretion, but *a priori* total congenital absence of the organ must have a cause much more deeply seated. The patient in this case was 20 years of age and had never passed through puberty. There were no secondary sexual characteristics. To exclude cryptorchism the patient was etherized and the inguinal canals broadly laid open. The stature

was 5 feet 9 inches and the mentality normal. The hips were broad; there was considerable panniculus and deposit of fat in the mammae. There was slight genu valgus, and while eunuchoids are infantile rather than feminine, the configuration of this patient suggested that of the opposite sex. The head hair, however, was masculine. The penis and empty scrotum were extremely small. The rectal touch showed absence of prostate and vesicles. There had never been libido, erections, or emissions. An x-ray of the skull showed an enlarged sella (compensatory overgrowth of the hypophysis?). The epiphyses were still distinct in the radiograms despite the patient's age. During exploration of the inguinal canal a well developed cord and vas deferens were discovered. At the extremity a minute nodule suggested the residue of a testis, but proved to be that of the epididymis. If the case was not one of true congenital aplasia the testes must have been completely destroyed by disease, but neither mumps nor other infection had ever existed. The patient had in fact enjoyed uninterrupted good health. There was not the least reason to accuse a partial hermaphroditism. The case was regarded as one of primary aplasia without any endocrinic component. The habitus was regarded as asexual and not feminine and patient was technically not a eunuchoid.

THE SAFE HANDLING OF TRINITROTOLUOL.

THE manufacture of munitions on a large scale has greatly increased the prevalence of poisoning by the nitro and amido compounds of benzol and toluol. It is therefore in the interests of health that employers using such poisons should endeavor by every means in their power to safeguard their workers from chronic poisoning. Dr. J. W. Schereschewsky, writing in *Public Health Reports* of November 16, 1917, indicates that the following precautions should be observed in order to reduce the risk of poisoning with trinitrotoluol to a minimum: (1) Planning and construction of workrooms: (a) Separation of processes; (b) conveyor systems. (2) Methods and processes employed. (3) Sanitary precautions on the part of the workers. (4) Hours of labor. (5) Medical supervision. With regard to the sanitary precautions to be observed, it is pointed out that the workers should be especially instructed concerning the value of scrupulous bodily and oral cleanliness. Men's hair should be kept short and their faces clean shaven. The hands and face should be thoroughly washed and the mouth rinsed out before eating, and a full shower bath should be taken at the close of the day's work. Proper facilities for this should be furnished. The teeth should be brushed twice daily with a soft toothbrush and a good dentrifice. Except in an emergency, no person engaged in an occupation in which trinitrotoluol is handled should work longer than eight hours a day. Workers engaged in hazardous processes should be changed to less hazardous work at least once in every two weeks, and oftener if necessary. An efficient system of medical supervision under the direction of a competent physician must necessarily be provided in all plants engaged in the manufacture and handling of trinitrotoluol.

News of the Week.

Smallpox in Florence.—A delayed dispatch to the press states that there has been an outbreak of smallpox in Florence, Italy, which seemed to be abating at the time the despatch was sent. Vaccine has been rushed to Florence from Rome by the American Red Cross, which fortunately had a sufficient amount on hand to respond to the appeal. The outbreak is said to have originated among the fugitives from the invaded region. According to the report all the schools of Florence have been closed.

Commissioner Emerson's Ruling Reversed by the Public Health Committee of the Academy of Medicine.—The Public Health Committee of the New York Academy of Medicine reports that while it has always been in favor of some method of regulation which would weed out inefficient private laboratories and would raise the standard of laboratory work throughout the city, it has opposed the ruling of the Health Department that the records of laboratories be open to inspection by the officers of the Health Department, with a view of ascertaining the number of cases of infectious diseases under the care of individual physicians. The committee has felt that this procedure is unwarranted at the present time and that no special gain would accrue from it.

Report on Food and Drug Act.—The annual report of the Bureau of Chemistry of the Department of Agriculture, recently published, shows the effect of this act in checking the spread of drug habits through the presence of habit-forming drugs in patent medicines. The report calls attention to the fact that in 1907 thirty soft drinks contained small amounts of cocaine. Practically all of these have been suppressed. Much has been done to control the indiscriminate use of so-called headache remedies, and of dangerous cosmetics laying claim to healing values. The act has made it possible to raise the quality of crude drugs through the examination of imports. As a result of cooperative work with the Post Office Department, a number of fraud orders were issued by that department preventing the use of the mails in promoting the sale of fraudulent medicines.

Infant Mortality Among Negroes in New York.—Since the summer of 1916 intensive efforts have been made to reduce the infant mortality in the Columbus Hill District of New York, which has a large negro population. The records of this district show that for the year 1915 the death rate among negro infants was at the rate of 314 per 1,000 births. Intensive efforts were then made for the control of this high death rate, with the result that for the year 1916 the rate was 168.50. For the year 1915 the infant mortality rate for the city as a whole was 202; for 1916, 193.3, and for 1917, 175.6 per 1,000 births, for the first nine months of the year. The infant mortality rate for the white population for 1915 was 96.2; for 1916, 90.7, and for 1917, 89.71.

Trudeau Tuberculosis Sanatorium in Paris.—The Red Cross formally opened the Edward L. Trudeau Tuberculosis Sanatorium in Paris, on December 25. The hospital has only eight beds at the present time, but it is hoped to increase the number to 1,200 within the next year. This is the first

tuberculosis hospital in France created wholly by the American Red Cross. Dr. James I. Gamble of Baltimore is at the head of the hospital and is assisted by American Red Cross nurses.

Illegitimacy in Prussia.—A cablegram to the *Associated Press* declares that, according to a statement made in the Prussian House of Representatives in the debate on vital statistics, 10 per cent. of the children born in wartime are born out of wedlock. The statistics show, however, that only 136 out of every 1,000 illegitimate children reach their nineteenth year, as compared with 512 in the case of legitimate children. Dr. Engel is authority for the statement that the unmarried mothers in Prussia now reach a total of nearly 200,000 yearly. By the devious processes of Teutonic reasoning this is interpreted as "Evidence of Moral Healthiness of the German Race." Dr. Engel is quoted as saying, "Paradoxical as it may seem, this great number of illegitimate children represents a measure of the morality of our people. They afford evidence that after all the idea of restriction of families, an idea which the war with special emphasis bids us combat, has not yet penetrated the masses."

Instruct Mothers in Milk Formulas.—The Infants' Nutrition Clinic of Vanderbilt Clinic organized some six months ago as one of the 130 babies' welfare units announces that it is prepared to establish classes for the instruction of mothers in the preparation of milk formulas. The clinic has enrolled 157 babies since its organization.

High Death Rate from Pneumonia Continues in New York.—For the week ending December 29 there were reported for the Greater City 2,521 deaths, of which 314 were caused by pneumonia. This is an increase of 56 over the preceding week.

Meeting to Discuss Charity Deficits.—The Federation for the Support of Jewish Philanthropic Societies has called a meeting of prominent Jews in New York to discuss means of raising additional revenue for the continued operation of Jewish charitable institutions. Reports from all the hospitals of the city as they come in show large deficits. Within a few days the Hospital for the Ruptured and Crippled reported a deficit of \$20,000, and made an appeal for funds. The Hospital for Deformities reports a like deficit. Felix M. Warburg announces that \$4,500,000 will be needed to insure a continuance of the work of the Jewish Philanthropic Society for the coming year.

The National Jewish Hospital for Consumptives, which is located at Denver, Col., will hold its annual meeting at the Savoy Hotel, New York, on January 13. Following the meeting, at three o'clock in the afternoon, a conference will be called to discuss "Tuberculosis and the War," at which addresses will be made by Miss Jane Addams, Dr. Herman Biggs, and Dr. Hatfield, secretary of the National Association for the Prevention of Tuberculosis.

Dr. Samuel W. Boorstein has been appointed adjunct assistant visiting surgeon to Fordham Hospital, New York.

The Salt Lake County Medical Association, Utah, at its monthly meeting, on December 10, elected the following officers: *President*, Dr. S. G. Kahn; *Vice-President*, Dr. J. O. Evans; *Secretary*, Dr. F. H. Raley; *Treasurer*, Dr. W. L. Rich.

The Kent County Medical Society, Rhode Island, at its annual meeting on December 13, elected the

following officers: *President*, Dr. H. Barton Bryer of Natick; *Vice-President*, Dr. Louis Legris of Phenix; *Secretary*, Dr. James M. Bodwell of Phenix; *Treasurer*, Dr. Frank B. Smith of Washington.

The Pacific Medical Journal, the oldest journal on the Pacific coast, which has just completed its sixtieth volume, will be consolidated with the *American Journal of Urology and Sexology*. The combined journal will be published from 12 Mt. Morris Park West, New York City.

Herter Lectures.—The faculty of the University and Bellevue Hospital Medical College announce that five lectures will be given under the Herter Foundation on "Principles Underlying the Treatment of Infected Wounds," by Edward K. Dunham, M.D., emeritus professor of pathology, University and Bellevue Hospital Medical College and Major Medical Reserve Corps, beginning on Monday, January 7, at four o'clock, and continuing daily at the same hour, at the Carnegie Laboratory, 338 East Twenty-sixth Street.

Dr. Guiteras Gives Bulk of Estate to Philanthropies.—The will of the late Dr. Ramon Guiteras disposes of an estate of more than \$100,000, the most of it going outside of his immediate family. The Columbus Hospital is to receive \$10,000 for a room to be known as the "Guiteras Operating Room." The New York Academy of Medicine receives \$5,000 for any purpose that may be desired and the Post-Graduate Hospital receives a like sum which is to go to the clinic with which he was connected at the time of his death. Dr. Guiteras left \$10,000 to Lenoncio Campuzano, a young man in whom he was much interested, on condition that he assumes the name Ramon C. Guiteras, half of the sum to be used in completing his medical education and one-half for his support when beginning the practice of medicine. The residue of the estate is bequeathed to the town of Bristol, R. I., for the erection of a school in memory of his mother, to be known as the "Guiteras School of Bristol."

St. Luke's Hospital, New York, is made the residuary legatee under the will of William H. White. The amount of this legacy is as yet unknown. Other bequests under the will include the following: St. John's Hospital, Brooklyn, \$20,000; Huntington Hospital, Huntington, L. I., \$25,000; Staten Island Hospital, New Brighton, \$40,000; Nassau Hospital, Mineola, L. I., \$10,000; St. Luke's Hospital, San Francisco, \$20,000.

Obituary Notes.—Dr. EVERETT JAMES MCKNIGHT of Hartford, Conn., died suddenly of heart disease, on December 25, at the age of 62 years. Dr. McKnight was a graduate of Yale and of the College of Physicians and Surgeons, New York, in 1879. While in college he was instrumental in arranging the first Yale-Harvard football game. He was a former president of the Connecticut Medical Association, and, in 1893, represented East Hartford in the Legislature. He was given the honorary degree of master of arts by Yale University, in 1907. It is thought that overwork in connection with the draft registration hastened his death.

Dr. ANDREW W. TRACY died at his home in Meriden, Conn., after a long illness, on December 10, at the age of 71 years. He was a graduate of McGill University Medical Faculty in 1872, and a former mayor of Meriden.

Dr. ERNEST ALBERT CRANSTON died at his home in Calais, Me., on December 14, aged 57 years. He was graduated from the College of Physicians and Surgeons in Boston, in 1905. He was health officer of Calais and coroner of Washington County, Me.

Dr. EDWARD M. HANSON, a graduate of the College of Physicians and Surgeons of Keokuk, Ia., in 1892, and a practitioner of Keokuk, died suddenly at the home of relatives in St. Louis, Mo., on December 11, aged 51 years.

Dr. A. D. MELVIN, chief of the Bureau of Animal Industry, died at his home in Washington, D. C., of pulmonary hemorrhage after a long illness, on December 7. Dr. Melvin was well known throughout the country because of his work in stamping out foot and mouth disease and pleuropneumonia plague among cattle. He also did much to promote the passage of our present meat inspection laws.

Dr. MARTIN A. MCGOVERN died of paralysis at his home in New York on December 16, aged 67 years. He was a graduate of Bellevue Hospital Medical College, in 1877, and a police surgeon of the New York Police Department until his retirement in 1916. Prior to his appointment to the police department he was attached to the New York City Department of Health.

Dr. HENRY A. DUNN, a medical inspector in the United States Navy and attached to the hospital ship *Havana*, which is now at the Brooklyn Navy Yard, died at his apartment in Brooklyn, N. Y., aged 43 years. He was a graduate of the George Washington University Department of Medicine, in 1897.

Dr. ENSIGN BENNETT PARDEE died of pneumonia at his home in New York, on December 28, aged 65 years. He was graduated from the New York University Medical Department, in 1875, and was a member of the American Institute of Homeopathy. He was visiting physician to the Homeopathic Hospital, Ward's Island, from 1890 to 1893, and to the Metropolitan Hospital, Blackwell's Island, from 1893 to 1897.

Obituary.

THEODORE CALDWELL JANEWAY, M.D.

BALTIMORE, MD.

Dr. THEODORE C. JANEWAY, formerly of New York City, died at his home in Baltimore on December 27, of pneumonia, after an illness of six days. He was born in this city on November 2, 1872, and was the son of Dr. Edward G. Janeway, who died in 1911. He was graduated from the Sheffield Scientific School of Yale University in 1892, and from the Medical Department of Columbia University in 1895. In 1898 he was appointed instructor, and later lecturer on medical diagnosis at the New York University Medical School. In 1907 he was appointed associate in medicine, and in 1909 professor of the practice of medicine at Columbia University. He was an attending physician at St. Luke's and the Presbyterian Hospitals. In 1914 he was called to the Johns Hopkins University to take the chair of medicine and to accept the appointment as physician-in-chief at Johns Hopkins Hospital on the full-time basis. Since our declaration of war he had been doing special research work for the Government,

having been commissioned major in the Medical Officers' Reserve Corps.

Dr. Janeway was secretary of the Russell Sage Institute of Pathology and a member of the board of scientific directors of the Rockefeller Institute for Medical Research. He was a member of the Association of American Physicians, of the Society of Experimental Biology and medicine, of the American society for the Advancement of Clinical Medicine, of the American Medical Association, and of other local and State medical societies. He was a diagnostician and clinician of the first rank, but was not a voluminous writer, his chief work being "The Clinical Study of Blood Pressure," published in 1904.

Correspondence.

PRACTICAL POINTS IN THE TREATMENT OF PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—At the present time, when pneumonia is increasingly prevalent, contagious, and deadly, it is right to express one's convictions where they may be most useful. For the contagion of pneumonia and for the relief of many patients, nothing equals beechwood creosote, properly and more or less constantly inhaled. In the way of heart stimulants there is none which equals tincture of strophanthus, old brandy, and coffee. It is not proven as yet that any other remedies can take their place satisfactorily. Science is one thing; art another. Science is constantly changing; art is not. One is based upon accepted, ephemeral conviction of the time; the other upon wise empiricism during many years and bedside observation and treatment of a large number of patients. The statements made by me are what I have affirmed more than once and with increasing conviction as to their great value when put into actual, daily practice.

BEVERLEY ROBINSON, M.D.

2. Studies of Infant Feeding.—H. I. Bowditch and A. W. Bosworth, carrying out their investigations in the Boston Floating Hospital Laboratories, found that one of the striking differences brought out by the comparison of the analyses of the feces of breast and bottle-fed babies is in the amounts of insoluble inorganic phosphorus found—feces from breast-fed babies having from 0. to 0.06 grams of P_2O_5 per twenty-four hours, while the feces from bottle-fed babies will show amounts depending upon the quantity of cow's milk fed; sometimes being as high as 1.0 gram P_2O_5 per twenty-four hours. They have determined that this insoluble

inorganic phosphorus is present in the form of calcium phosphate. Since it has been shown that insoluble dicalcium phosphate is present in suspension as a normal constituent of cow's milk, and is not a constituent of breast milk, the question came up as to whether the large amounts of phosphates present in the feces in bottle-fed babies are due directly to the insoluble phosphates present in the cow's milk used, or to other causes. The investigation of which this is the resulting report was undertaken to ascertain if dicalcium phosphate is available as a food when present as a constituent of infant's food. It has been previously shown by Van Slyke and Bosworth that cow's milk contains 0.175 per cent. of dicalcium phosphate (CaHPO_4), and in this paper it has been shown that this phosphate was not available as a food to children under four months of age, and only partly available phosphate by the older children is probably dependent upon the more abundant secretion of hydrochloric acid. In connection with the results reported here, it is of interest to consider the fact shown by Bosworth—that human milk, unlike cow's milk, contains no dicalcium phosphate, the mineral elements in human milk therefore being completely available as food for infants. In calculating the amount of mineral elements present in modified cow's milk for use in infant feeding, the dicalcium phosphate should be considered as unavailable, and a corresponding deduction made from the total mineral elements in milk. They have shown that during the process of digestion of calcium caseinate the calcium and phosphorus contained within the calcium caseinate may unite to form insoluble calcium phosphate and appear in the feces as such, the calcium and phosphorus balances under these conditions becoming negative. They have also shown that by feeding a large amount of soluble calcium it is possible to precipitate practically all the phosphorus in the food as insoluble calcium phosphate, this substance being eliminated in the feces, and as a result of this the metabolism of phosphorus is reduced to such a low level that the urine becomes phosphorus-free.

6. Sporadic Pellagra. M. E. Alexander.

5. Highway Accidents in New York City.—Shirley W. Wynne has investigated conditions relating to mortality results from highway accidents in New York, and says that the number of accidents in this city caused by horse-drawn vehicles has decreased since 1907. The decrease has been accompanied by an increase in the number of accidents caused by automobiles. The number of accidents caused by automobiles has increased, but the ratio of automobile accidents to automobiles operated has very markedly and very steadily decreased since 1908. The increase in pedestrian traffic in certain districts of the city, business, theatre and shopping, has been a most important factor in causing the increase in highway accidents. It is quite clear that as the congestion in these districts increases, additional measures for the prevention of accidents must be instituted, because, while the present traffic regulations are the best that can be devised under present conditions, they increase to a very great extent the conditions they seek to overcome; in other words, the necessity of shutting off north and south bound traffic to permit east and west bound traffic to pass increases congestion on the avenue, which is still further augmented because traffic is not stopped and started at all the streets crossing the avenue at the same time. His recommendations for the improvement of such conditions are as follows: (1) More stringent enforcement of the traffic regulation and the vigorous prosecution of reckless drivers. (2) Amendment to the present traffic regulations forbidding pedestrians to cross streets elsewhere than at the crossings and to cross streets except in accordance with the signals of the

traffic officers stationed at the crossings. (3) Provision of more public parks in the congested areas of the city. (4) The above recommendations are but palliative, and in order to permanently improve traffic conditions, to prevent the immense yearly toll of traffic accidents in injury and death, to increase efficiency and comfort of travel in the city streets, more radical measures must be adopted, such as the old suggestion of sinking the cross streets below the level of the avenues in congested districts; the building of at least one subway in Manhattan for north and south bound traffic, this subway to be reserved for traffic between distant points by having entrances and exits not less than ten blocks apart. Some time ago the Police Commissioner suggested a viaduct or elevated roadway for north and south bound traffic. While it would be less expensive than a subway, it would create greater opposition upon the part of owners of property fronting on the avenue upon which such a viaduct might be built, as it is generally conceded that elevated structures have depreciated property values on every avenue or street on which they have been built. Until some such radical methods of handling traffic in congested districts are adopted, traffic accidents, other than those due to speeding and reckless driving, cannot be eliminated.

7. Physically Handicapped Children: Recommendations for Outdoor, Fresh-air and Open-window Classes.—Adela J. Smith, Frances Cohen and I. H. Goldberger, having deduced their results from their work in connection with the Department of Physical Training and Educational Hygiene, Department of Education of New York City, state that among the 800,000 children attending the public schools of this city, there are hundreds of physically handicapped children, including those affected with active pulmonary tuberculosis, and with bone, skin, and glandular tuberculosis. There are also many pretuberculous, anemic, and crippled children, and cardiac cases. As these children cannot attend the regular classes, provision must be made for their comfort, health, and progress by some process of segregation into special classes, of provision of special classroom and personal equipment, and a relaxed curriculum. Because of the varied types of physical defects, and of the different kinds of treatment necessary, these children cannot be grouped in any one type of classroom, but are divided into groups according to their physical or mental handicap. Thus outdoor classes, fresh-air classes, and open-window classes are formed. Crippled children are provided with transportation by stage to school and to their homes. The furniture now in use for classes of crippled children in the New York City public schools has solved the problem with reference to the braces and supports used on these cases. Both desk and seat have a central floor support, instead of the side supports of regular furniture, and are fastened to the floor. This provision leaves ample floor space, both for the locomotion of crutch patients, and for full extension of rigid limbs of brace patients, when the latter are seated. Aisle spaces should not be less than twenty-four inches wide. The desk top is so constructed that a variable plus or minus distance of great range may be instantly obtained to meet the

special seating needs arising from the mechanical appliances worn by the crippled child. The seat is provided with an adjustable back, similar to that of a Morris chair, with a cane center to prevent undue pressure. This cane back is removable, so that all pressure on sensitive spines may be prevented. When greater warmth is necessary, children in all open-window classes should be provided with sweaters, coats, leggings, mittens, caps and bloomers for the girls, in addition to their skirts. As these are articles of clothing in common use, no additional expense for personal equipment is needed. The personal equipment of the teacher should be similar in character to that worn by the children in the special class to which she has been assigned. These and many other improvements for the benefit of handicapped children are being carried out in the New York schools, and these writers group their recommendations for this beneficial work as follows: (1) The type of physical defect should be the basis for the segregation of groups of physically handicapped children in special types of classrooms, that is to say, outdoor, fresh-air and open-window classrooms. (2) The range of temperature is governed by the type of physical defect in each special group. (3) Glass wind and storm shields are recommended to admit light and regulate heat, replacing the canvas or wood protectors now in use. Specially constructed window ventilators should be installed in all open-window classes, to prevent drafts and to protect children seated near the open windows. (4) No classroom for physically handicapped children, with the exception of the kind mentioned in Groups 1 and 2, of the third section in the accompanying table, should be located higher than the second floor unless an elevator is available. (5) In outdoor and fresh-air classes, movable, adjustable chairs are recommended instead of fixed desks and seats. This equipment could then be used for sleeping, rendering but one set of classroom furnishings necessary. A movable equipment in outdoor and fresh-air classrooms has the following additional advantages: (a) Direct drafts on children are easily avoided. (b) Greater space for classroom activities and physical training is provided. (c) The children are permitted greater freedom. In classes for cripples, additional mobility is made possible through specially constructed desks and pivotal chairs. (6) The type of personal equipment should allow the greatest possible freedom for schoolroom activities and physical exercises, and should eliminate the danger arising from fire drills and other emergencies. It should also be sanitary, so as to be easily cleaned. The type of equipment commonly in use fulfills none of these requirements. Before a child is placed in a special classroom with lowered temperature, he should be provided with sufficient underwear and appropriate outer clothing, as well as storm equipment, so that he may not feel the effects of exposure when he leaves the classroom at the end of a school session.

2. Serum Disease after Intrathecal Injections of Serum.—H. D. Rolleston states that during the third year of the war out of ninety-six bacteriologically proved cases of cerebrospinal fever treated by serums and surviving for ten days or more, fifty-eight, or 60 per cent, had a serum reaction, as judged by the appearance of a rash. Among these fifty-eight cases there were nine, or 15.5 per cent in which the rash was preceded or accompanied by a more or less definite recrudescence of meningitic manifestations, thus, especially when preceding the rash, suggesting a relapse of the disease. These symptoms are relieved by lumbar puncture, and under the assumption that they point to a relapse a fresh injection of serum may be

given, as was done in six out of the nine cases. The three cases not so injected recovered, and of the six cases injected intrathecally with serum, five were probably made worse, four eventually proving fatal, though it is not suggested that death was thus induced. The effect of intrathecal injection of serum presents some peculiar features. Whereas, as is well known, injection into a healthy intrathecal space sets up an aseptic chemical meningitis, injection of anti-meningococcal serum in cerebrospinal fever—as is shown by the clearing of the cerebrospinal fluid—reduces the inflammatory process, presumably by destroying the meningococci. Injection of immune serum into slightly inflamed meninges sets up in most cases an acute aseptic meningitis shown clinically by fever, rigidity of the neck, and other signs of meningeal irritation. It is, therefore, desirable to have some means of determining whether there is a genuine relapse which will be benefited by serum or whether the condition is one of meningeal irritation or meningism and a manifestation of serum disease which may be intensified by a further injection of serum. He has decided that (1) Symptoms of meningeal irritation may precede or accompany the appearance of the serum rash. (2) Though serum disease is frequent after intrathecal injection of serum, especially after Flexner's antimeningitis serum, it is not clear that it is more frequent than after hypodermic injection of serum. (3) Intrathecal injection of serum necessarily involves risk of inducing increased intracranial pressure and may introduce a secondary infection; but it is not proved that the volume of serum injection favors a secondary infection of the meninges from the blood-stream.

2. The Treatment of Neurasthenia and Psychasthenia Following Shell Shock.—R. T. Williamson tells that a very large number of cases of persistent neurasthenia, psychasthenia, and allied conditions, following shell shock are now under treatment in England. Similar affections are also caused by the shock or continued anxiety of Zeppelin raids, and also the continued anxiety from other risks of injury. The symptoms may commence suddenly after one severe shock, or gradually after repeated shocks. In many of the severer cases the patient is unable to carry out either military or civil duties for a long period and so keeps up an extended pension. It is thus important both for the patient and the country that a cure be effected as soon as possible, and the cure should be psychological as well as medical. Williamson offers a method of treatment which briefly outlined is as follows: (1) All anxiety and fear of further exposure to similar risks to life, and anxiety from other causes, should be removed if possible, and the patient should be definitely told that he will certainly recover. (2) The sleep treatment is very useful. At first hypnotic drugs may be given both at night and during the day for a short time; so that the patient may sleep all night and, for a few days, also during part of the daytime. (3) He should cease thinking of the war and his experiences. This may be brought about (a) at first by the sleep during part of the daytime as well as during the night as just described, and by occupation whenever he is awake;

(b) afterwards he should be kept asleep all night (by drugs); but during the day the drugs should be discontinued and he should be kept fully occupied in a suitable way. (4) As regards the kind of occupation: (a) A new subject or one not associated with his war experience is desirable. (b) *Very close application* to the work in hand is important. (c) The occupation should be one requiring thought, and if the patient finds, after continuing it for some time, that it can be done mechanically, the occupation should be changed or altered so that thought is required. (d) It should be one very interesting to the patient, and one which will become more interesting.

La Presse Médicale.

November 8, 1917.

Prognosis in Chronic Renal Tuberculosis.—Hallé concludes his article with the following paragraph: One may not dogmatize in therapeutics. Medical history for the past thirty years has taught that the verity of today is the heresy of tomorrow. It is a condition essential to progress that applied science never reaches its mark. A univocal therapy is neither scientific nor empirically successful. Chronic tuberculosis is not incurable. The closed inaccessible types become isolated and harmless; the open types may be evacuated when accessible. Incurability is a false theory. The general truths concerning pulmonary tuberculosis may be so construed as to apply to the kidney. The polymorphism in both localities is comparable. Our treatment of renal tuberculosis today is surgical but there is no reason why we shall not some day have a medical treatment as well. The shelved distinction between medical and surgical tuberculosis will come back. The former, like pulmonary tuberculosis, may be able to recover spontaneously or be curable by medical measures. This form represents either the closed focus or a hematogenous infection. Surgical tuberculosis cannot recover without surgical intervention by nephrectomy. It is either an open pelvic tuberculosis or a lymphogenous lesion.

Malignant Endocarditis of Slow Evolution.—Debré states that this affection is still but little known and is missing in classic reference works. It may be completely overlooked in diagnosis; or when recognized it may be regarded erroneously as something interesting in its rarity, something atypical. Yet according to an American writer, no affection is more stereotyped. The author is writing a separate paper on the disease picture and his present effort is rather to call attention to a neglected subject. Protracted malignant endocarditis, requiring several months for its evolution, was described by Jaccoud in 1882. For the next twenty years no serious heed was paid to this disease entity in France. There was then a renaissance among French clinicians, and in 1903 Gouget's monograph on the subject appeared, since which event the profession in France have made many contributions. Among English writing authors, Osler is easily the first to make known this affection, both in point of chronology and sustained interest, and a long series of Americans have aided in the development of our knowledge. The Germans, represented by von Leyden and Litten, had an inkling of the nature of the malady at the same period as Jaccoud, and Litten's publication in 1881 is apparently the oldest. For the full development of the subject, Lenhartz (1901) is given the priority in his country, while the classical work of Schottmüller is as recent as 1910. Some of the data of maximum interest are as follows. The disease as a rule attacks subjects with traces of rheumatic endocarditis. It usually has a determining focal infection—in France—apparently an angina, laryngitis or bronchitis (dental and sinus infections do not seem to have been recorded outside of America). It is a general or systemic failure which causes the patient to seek treatment and the prostration and cardiac implication have only too often caused a diagnosis of grippe. When slight joint troubles coexist this error is much less likely to happen. Osler was the first to describe the cutaneous symptoms (purpura, erythema nodosum). Pseudo-felon is an interesting digital manifestation. There will constantly be found an enlargement of the spleen in some degree which if

misunderstood may cause a diagnosis of pernicious anemia owing to the coexistence of pallor and purpura. The endocarditis, with possibility of embolism, etc., does not differ essentially from that seen in less chronic septic conditions and to a certain extent the two processes show parallelism, for example, in the production of infants in the spleen and kidneys.

La Presse Médicale.

November 15, 1917.

Omnibus Treatment of Stomach Affections.—Meunier isolates an all important symptom in gastric pathology, to wit, *delayed pain*, i.e. distress which supervenes some time after eating. It may consist of a burning sensation, a heaviness or a mere malaise and is present in most gastric affections whether neoplasm, ulcer, ptosis, Reichmann syndrome, pyloric stenosis, etc. (he does not specify duodenal ulcer). It is this *delayed distress which brings the patient to consultation*. The author seeks a *rationale* for this subjective symptom—which is present alike in structural and functional maladies—in order to institute some general plan of relief. The first resource applied was cryoscopy of the gastric juice and normal stomach contents were first investigated. According to Raoult's law the freezing point depression of a solution is proportioned to the number of molecules in that solution. The author studied the cryoscopic curve of the stomach contents after repasts of carbohydrate food (bread) and protein (meat) respectively. Twenty normal men were placed on an exclusive regimen of bread and the stomach contents tested at intervals. At the end of 10 minutes the cryoscopic point was 0.70, a maximum, after which it declined progressively until at 1½ hours it was 0.38. In other words, as digestion progresses this point declines until a theoretical minimum of 0.35 is reached (in fact it never is quite attained). If now normal subjects are placed on a meat diet conditions are reversed. At the end of 10 minutes the cryoscopic point is 0.12 and at the close of 1½ hours it is 0.34. The theoretical maximum of 35 is never quite attained. Hence under both plans of diet the act of digestion brings about the same result. In making a comparison between sound and sick subjects, we take the cryoscopic point at about 1½ hours after a meal. The author's view is that at this period the normal stomach is evacuated irrespective of the character of the diet. Studies of cases of cancer, stricture of the pylorus, ptosis and Reichmann's syndrome show from this mode of research that the stomach is not evacuated on time, which fact explains the painful sensations; these resulting from persistence and abnormal concentration of stomach contents. Upon this theory the remedy is self-evident—the contents should be diluted to the proper concentration by the ingestion of solutions which have a cryoscopic point of 0.35. Sodium chloride solutions should be of 5.5 parts per 1000, sodium citrate 20 parts per 1000, phosphoric acid 26.80, peptone 40, etc., etc. The patient drinks a claret glass of any of these solutions every 10 minutes. The choice of solution may depend somewhat on the nature of the malady. The author claims that pain must often be relieved before a diagnosis can be made and admits that in certain cases the routine use of alkalies gives better results. Nevertheless the plan has much value as a routine resource and will give positive results in a great variety of cases.

Enterococcus Infections.—Tricoire refers to a pseudotypoid infection not due to paratyphus bacilli or other familiar bacterium. The cause is the enterococcus of Thiercelin, a germ which stands midway between the pneumococcus and streptococcus. In *vivo* it is a diplococcus, and in *vitro* a diplostreptococcus, while in very old cultures it appears to be a diplobacillus. In other words it is essentially a bacillus which in its youth appears as a coccus (for the bacillus can hardly be looked upon as a degenerate formation). Its discoverer, Thiercelin, has written at much length on its cultural

qualities and pathogenicity to animals. It supplies a heat-fast toxin and shows high resistance to ordinary antiseptics. It causes local suppurative and septicemia. It is a saprophyte in the intestine of man and is found in the soil—in fact, with the colon bacillus it is one of the fundamental denizens of the intestine. It is even believed to be one of the animal defences and to play some physiological rôle in the intestinal equilibrium. Just when and how it becomes virulent we can only surmise; but we know it does become so, causing local or general mischief. It is found in great numbers in certain cases of acute gastroenteritis in nurslings. Years ago Lesage described a diplococcus enteritis evidently due to the enterococcus. The latter is also able to cause mucorhemorrhagic enteritis and acute colitis, and has been known to set up cholungitis, infectious icterus, peritonitis, etc., and has been accused of causing various chronic conditions in the abdomen, notably cholelithiasis and chronic hepatitis. Choleric syndromes and alimentary intoxications have also been associated with the enterococcus. So-called intestinal grippe has been found to be associated with the latter. The septicemic form may be secondary to local manifestations or may occur *d'emblée*. Its expression may be generalized or localized in a particular organ or system. It is able to cause a metastatic and noninfectious arthritis, the nature of which is not yet determined. Probably the discharge is secondary to a focus in the epididymis or vas deferens. An entire series of acute respiratory lesions may be set up, including abscess of the lung, phlegmonous laryngitis, bronchopneumonia (pseudolobar) of a highly specialized type indicating a severe constitutional infection. The condition tends to become chronic and simulate tuberculosis. The enterococcus can also cause a septic rheumatoid of a more acute type than that due to the *viridans*. Essential sepsis due to the enterococcus tends to occur with and complicate typhoid and paratyphoid fevers.

Does Prolonged Use of Antipyretics Alter the Excitability of the Heat Center?—Lüthy, a dentist, has studied this problem in the Pharmacological Institute of the University of Zürich (Professor Cloetta). The method of research consisted in treating laboratory animals with pyramidon and the results are announced as follows: If animals (rabbits) receive daily injections of large amounts of pyramidon, the heat center develops no change in its excitability as shown by the fact that intravenous injections of *B. tetrahydronaphthylamine* and putrid hay infusion given before and after the daily pyramidon dose cause the same temperature rise. If by daily injection of the first named thermogenic substance fever is regularly produced and then antagonized with doses of pyramidon, a gradual diminution of the action of the fever producing drug is witnessed. If hay infusion is used to produce the fever and if pyramidon is given to antagonize the fever no change is witnessed even after prolonged exhibition in the pyretogenic result of the said infusion. Hence, if the cause of the fever is bacterial drug antipyresis does not disturb the ability of the heat center to react, nor need we fear that use of the drug for this purpose will mask the presence of the fever. The withdrawal of the drug will not affect the fever curve. If, however, a definite drug is used which exerts a selective action in the region of the fourth ventricle an antipyretic drug can depress the excitability of the heat center.

Nitrobenzole as Abortifacient.—Spinner relates 14 cases of severe poisoning from this drug when used with criminal intent. The earliest goes back to 1866 (unreported until 1876) and occurred in a girl of 18 who, when 5 months pregnant, took 10 grains of the drug. Pregnancy was not interrupted but the girl was severely poisoned with cyanosis as a prominent symptom. Lesser reported two cases in which two women took supposed oil of bitter almonds for abortifacient effect. Only one was made ill, dying in 10 hours and it was learned that she had taken pure nitrobenzole. This second woman proved not to have been pregnant. It was a mystery how the two women managed to drink different poisons when they presumably swallowed

the same substance in the same dose; but nitrobenzole alone was found in the stomach of the dead woman, while her friend, whose life may have been saved by prompt vomiting, passed urine containing hippuric acid, as would naturally happen when bitter almond oil is swallowed. Look reported a fatal case which was also attended with obscurity. The gravide had applied to a quack for an emmenagogue but had obtained the poison directly from a druggist. Nearly all of the latter was present in the cadaver at the autopsy. Several other cases show some element of mystery. In one the intent seems to have been suicide, although the woman was gravid. The author is familiar with a case reported in 1913 in which the history is fairly complete. A woman of 42, married, took a small dose of "oil of mirbane" with abortifacient intent. When seen soon afterward she smelled strongly of kernels and was markedly cyanotic and collapsed. Her temperature was subnormal. The mental state was one of apathy with occasional outcries. Epileptiform convulsions succeeded one another at intervals. Treated with saline infusion, oxygen and camphor injections she soon improved. The urine contained abundant urates, urobilin and urobilinogen. Gestation was not disturbed. The drug had been purchased as oil of mirbane (nitrobenzole) and not as oil of bitter almonds. The first named, as is well known, is largely substituted for the latter because of the similarity of the odor. According to the author nitrobenzole is without any abortifacient properties and can destroy fetal life only when the mother is fatally poisoned.

Developmental Cycle of the Dibothriocephalus Lotus.—Janicki and Rosen refer to the interest possessed by this subject in the 80's, when it was shown that this parasite was a normal denizen of certain food fish, whence it passed into the intestines of the dog, cat, and man. The parasitism of the worm in the fish could not be explained, for the embryos could not be made to infect trout, pike, and other fishes. Recently the authors have taken up this problem at the point where it was abandoned. Recent ciliated embryos from human feces were subjected to intensive cultivation and attempts were made to infect directly trout, perch, etc., and it was thought that the absolute immunity shown might be due indirectly to the predatory nature of these fishes, who are natural hosts for the bothriocephalus. In other words, these fishes may become infected in a state of nature because of eating other kinds of fish already infected. The natural prey of lake trout, pike, etc., are certain species known as white fish. Attempts to infect the latter with embryos met with failure. A thorough survey was then made of the bodies of hundreds of river perch and other fishes which naturally harbor the parasites in the hope of finding an intermediate host, and suspicion rested on certain invertebrates. The authors succeeded actually in isolating an undescribed development (larval) stage of the bothriocephalus and were finally able by this find to discover intermediate hosts in the form of certain Copepoda, to wit, a species of Cyclops and a species of Diaptomus. Both these are at times found almost to the exclusion of other food in the stomach contents of perch. In cases in which other food such as the Daphnides was present to the exclusion of the preceding the new larval stage of the tapeworm was never isolated. The nature of this larva makes intelligible the fact that it can readily pass from the alimentary canal into the muscle and liver of the fish and become encysted. In this locality it can readily infect man. It has long been known that Copepoda can act as hosts for certain Cestodes. After numerous species of Cyclops had been investigated in vain the *C. strenuus* was found to contain from one to ten oncospheres, and the problem was in part solved. A second host was found in the *Diaptomus gracilis*. The cycle of the bothriocephalus in these invertebrates could be shown in full, and it now only remained to infect the fishes. Very young trout were placed in a medium containing large numbers of infected intermediate hosts which they rapidly devoured. They could then

be examined at stated intervals. The first trout, taken from the water in 5 to 6 minutes, already showed free larvæ in the stomach. These proceeded to attach themselves to the mucosa. By the second day they were already in the submucosa and in a few days more in the muscular coat and liver. The subsequent stages have long been known, and the crucial find in the research was not so much the infected Cyclops as the unsuspected larval form of the tapeworm.

The Treatment of Chronic Gonorrhea and Urethral Stricture by Thermic Sounds.—Rost has obtained excellent results by Kobelt's method (*Münchener medizinische Wochenschrift*, No. 30, 1912). The writer, after varied trials, has adopted the following method: In cases of chronic gonorrhea the largest possible sound is introduced two or three times a week, heated at 120° to 130° F., and retained in the urethra for 20 minutes to one-half hour. When beginning the treatment, flexible sounds are used, and it is only later on that rigid instruments are substituted. The number of treatments necessary varies from ten to thirty, according to the gravity and chronicity of the given case. This treatment does not necessitate giving up the use of the silver salts during its application. Rost attributes the happy effects of this treatment to the hyperemia produced and the detergent action resulting from the profuse secretion which is set up. Rost promises a description of this treatment in gonorrhea in the female in a future paper. The procedure is excellent to provoke an acute outburst and to detect a latent gonorrhea, and in this respect it surpasses the means ordinarily employed for this purpose. The writer declares that, from his researches, he can affirm that 33 per cent. of cases of gonorrhea considered cured clinically still continue to hide the gonococcus in the urethral mucosa and, therefore, are dangerous from the standpoint of contagion. The thermic sound will expose this danger at the same time that it counteracts it.

Serum Disease.—Ewald relates his findings made during serum treatment of dysentery. He insists upon the tumefaction of the spleen and lymph nodes. The classic incubation (8 to 10 days) has been found unreliable, and in reality varies between 5 and 15 days, or even less or sometimes more. The writer reports two cases having a classic symptomatology, respectively with a relative lymphocytosis of 11,200 and 7,900 and normal eosinophilia. From the theoretical viewpoint, Ewald tries to explain serum disease by an extraordinarily intense disintegration of the injected albumins into peptones. The latter products set up the reaction to which the name of serum disease has been given. Finally, Ewald does not believe that the apparent gravity of certain cases is a contraindication to the use of antidyseric serum, although this product cannot be as yet produced in as concentrated a form as antidiphtheric serum.

October 8, 1917.

The Treatment of Bone Cavities Containing Sequestra.—O. Hilderbrand has endeavored to produce an intensive formation of granulation tissue by opening the wall of the bone cavity which is in close proximity to the soft structures. Thus in the case of a sequestrum on the tibia the writer is not content merely to open the bone in front, but makes one or several small fenestræ on the posterior aspect of the bone. The cavity then fills rapidly by granulation tissue which proliferates through these openings. In order to assure a more solid consistency to the bone, the skin around the opening in the bone is mobilized and the borders are inserted and fixed into the bone cavity.

The Leucocytic Formula and Fever in Malaria.—Hülse has studied the evolution of the temperature, the variations in the leucocytic equilibrium and the elimination of figured bodies during paroxysms of malaria. From these studies it would seem that the initial leucopenia (3700) takes the place of a relative leucocytosis (7200) at the beginning of the rise of

temperature. The leucocytes rapidly diminish in direct relation to the febrile elevation (800 leucocytes when the temperature attains 104° F.). When the temperature has returned to the normal there is likewise a return of the white corpuscles to the initial numbers. Regarding the various leucocytic types, the writer observed that the invasion resulted in a "derivation to the left" of the leucocytic formula, that is to say, the presence of a greater proportion of young polynuclears. He concludes that there is a great destruction of the leucocytes at the time of the febrile paroxysm. This view is confirmed by the enormous elimination of figured bodies which takes place at this time. Finally, Hülse establishes a causal relationship between these figured bodies and the hyperthermy. Quinine seems to prevent the thermic crisis by insensibilizing the thermic centers by the thermogenous action of these bodies.

Deutsche medizinische Wochenschrift.

October 11, 1917.

Weil's Disease, Recurrent Fever, and Bilious Typhoid.—E. Hübener reviews the similarity and dissimilarity of Weil's disease and recurrent fever. They are related by their etiology (spirochetes), their acute aspect, their noncontagiousness, the morbid changes arising in the abdominal viscera, their serological characters (antibodies, both agglutinating and fixing and destructive to the spirochetes). Serotherapeutic treatment and Wassermann's reaction are negative in both processes. Their identical duration of incubation (about one week), their clinical symptomatology so similar, bring them still closer together. Regardless of these points in common, the two affections, however, offer very marked differences. The typical defervescence of Weil's disease is in evident contrast with the crisis of recurrent fever, while the suddenness of the relapses of the latter malady is quite in opposition to the slower invasion of the paroxysms of Weil's disease. Besides, the recurrent type of fever is more precocious in recurrent fever, and icterus may often be absent in this affection, while it is more constant in Weil's disease, and also more intense. On the other hand, in the latter affection there is no edema of the legs, a frequent symptom in recurrent fever. The differences become still more evident by the characters of the spirochetes giving rise to each of these morbid processes. Now, while recurrent fever is favorably influenced by salvarsan, this drug is useless in Weil's disease. The epidemiology and pathological anatomy of the two diseases are quite distinct. On the other hand, Hübener admits the identity of Weil's disease and bilious typhoid. The epidemiological characters make this affection a distinct disease from recurrent fever, but Weil's disease may certainly comprise not only bilious typhoid but various other febrile affections as well, namely, the so-called bilious fevers.

Functional Exploration of the Liver.—H. Gerhartz finds that the ingestion of 80 grams of levulose may give rise to urobilinuria of characteristic type, resulting from a certain degree of hepatic morbid change. It is quite sufficient to analyze the urine voided from two to three hours after ingestion of the drug, in order to detect the changes.

Rarity in Soldiers of Sympathetic Ophthalmia.—Morax in 1,500 examinations of soldiers with eye injuries has found but 1 case of sympathetic ophthalmia. This result must be due largely to the number of enucleations required.—*Annales d'Oculistique*.

Fever as a Curative Factor in Syphilis.—Kyrle restates the long-known discovery that febrile states exert a favorable influence on cutaneous and mucous syphilides, even in the absence of specific treatment. The alleged benefit from fever in metasyphilis may be of the same nature. Biach has used tuberculin in secondary syphilis with good results. The present author in order to produce fever has used injections of foreign protein (mild), mercury and salvarsan, and has caused the Wassermann to become negative. He believes that fever is of value only when produced by antisiphilic remedies.—*Wiener klinische Wochenschrift*.

Book Reviews.

LIGATIONS AND AMPUTATIONS. By A. BROCA, Professeur d'Opérations et Appareils à la Faculté de Médecine de Paris. Translated by ERNEST WARD, M.A., M.D., F.R.C.S. Octavo of 285 pages with 510 illustrations. Price \$3. New York: William Wood & Company, 1917.

THIS is a book of particular interest just at the present time, since the technique of ligations and amputations should be thoroughly known by all members of the Medical Reserve Corps who are at all likely to have active war service. These subjects are presented in detail in Broca's book and practically all essential features of the technique of individual operations are illustrated. The book is divided into two sections; the first covering the ligation of arteries; the second, amputations and disarticulations. The second section is again divided into three parts under the headings: General Observations; Amputations in Continuity; and Disarticulations. Broca's long experience as a teacher has enabled him to cover the different portions of the subject briefly or in minute detail, with a nice discrimination as to the amount of space to be allotted and the relative importance of the various subjects; while the book is still further enriched through material added on the basis of Broca's experience during the present war. The essential anatomical facts are briefly stated, then the technique of the individual operation, together with a running commentary giving many practical points. Concerning the latter, we agree with Broca's translator when he says in his preface: "It is chiefly a knowledge of little points which makes the difference between the recently appointed hospital surgeon and the man with several years' experience on the staff." This book appears at a very opportune time, is of convenient size, well printed, and profusely illustrated, and should be a great help to those preparing for war service.

RADIUM THERAPY IN CANCER AT THE MEMORIAL HOSPITAL, NEW YORK. By HENRY H. JANEWAY, M.D. with the Discussion of Treatment of Cancer of the Bladder and Prostate by BENJAMIN S. BARRINGER, M.D., and an Introduction upon the Physics of Radium by GIOACCHINO FAILLA, E.E., A.M. Price, \$2.25. New York: Paul B. Hoeber, 1917.

THIS report of the Memorial Hospital, New York, deals with the methods of applying radium to malignant tumors in different situations. It gives details concerning the concentration of radium to the unit of surface, the exact nature of filtration, the exact periods of repeated applications, and the successive steps of the therapeutic result. It is obvious now, as the authors point out, that the successful use of radium in cancer requires careful consideration of each particular type of the disease in each organ as separate problems, in which different methods must be devised and different results expected. Hence, in this work, the various forms of cancer are separately considered, and the indications, methods, complications, and results are given briefly for each. This report should prove very valuable to those who have sufficient knowledge of radiology to appreciate its significance, but in order that the uninitiated may derive useful information from it Dr. Failla has given a brief introductory account of the principal phenomena of radioactivity.

A MANUAL OF PERSONAL HYGIENE. Proper Living Upon a Physiologic Basis. By American Authors. Edited by WALTER L. PYLE, A.M., M.D., Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia; Assistant Surgeon to the Wills Eye Hospital, Philadelphia, etc. Seventh edition, revised and enlarged. Price, \$1.50. Philadelphia and London: W. B. Saunders Company, 1917.

THE new edition of this work is larger than the previous edition by about ten pages. A few paragraphs on infantile paralysis, grip and pneumonia, and cold in the head have been added; and a small number of minor changes have been made in the text. The revision is of the very slightest, and we observe that the price of all kinds of foods, in Philadelphia, is the same

now as it was when the second edition was issued, in 1901. The index (and presumably, the book itself) is entirely innocent of any such entries as caloric, obesity, sexual or social hygiene, gonorrhea, syphilis, venereal diseases, prostitution, social evil, etc. Twenty years ago these latter topics had not assumed (in the eyes of the public) the importance which they have to-day; but at the present time a book on personal hygiene which studiously omits any reference to these subjects is rightly considered incomplete.

DISEASES OF THE CHEST AND THE PRINCIPLES OF PHYSICAL DIAGNOSIS. By GEORGE W. NORRIS, M.D., Assistant Professor of Medicine in the University of Pennsylvania, and HENRY R. M. LANDIS, M.D., Assistant Professor of Medicine in the University of Pennsylvania, with a chapter on the Electrocardiograph in Heart Disease, by EDWARD B. KRUMBHAAR, Ph.D., M.D., Assistant Professor of Research Medicine in the University of Pennsylvania. Price, \$7.00 net. Philadelphia and London: W. B. Saunders Company, 1917.

THIS book is divided into two sections, the first being devoted to a detailed description of the principles and practice of physical diagnosis, while the second and larger section takes up seriatim the diseases of the chest. The first is written by Dr. Norris; he draws extensively from the domain of physics in order to explain the phenomena of inspection, palpation, percussion and auscultation. Although there is nothing new in the author's exposition of physical diagnosis, yet at the same time the data which has been collected is presented in a very readable form and is rather different from the usual stereotyped version. A noteworthy feature is the illustrations, many of which are original. Photographs of frozen sections of the chest are utilized in visualizing physical signs observed in the various diseases subsequently considered. By way of criticism it seems to us that the chapter on blood pressure and use of instruments such as the sphygmomanometer, sphygmograph, and polygraph is dismissed too briefly. We can find no mention of pulse pressure and its significance. A short chapter on the electrocardiograph, written by Dr. E. B. Krumbhaar, is included in connection with the examination of the circulatory system. One of the best chapters in the first section is that on cardiac murmurs, which are lucidly illustrated by diagrams and photographs. The second part, dealing with the diseases of the chest and written by Dr. Landis, is concerned with etiology, morbid anatomy, physical signs and diagnosis. The diseases considered are those of the bronchi, lungs, pleura, pericardium, myocardium, endocardium, congenital heart disease, angina pectoris, aortitis, and aneurysm of the thoracic aorta. The illustrations of pathological specimens are especially to be commended.

THE PRACTICAL MEDICINE SERIES, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume V. PEDIATRICS. Edited by ISAAC A. ABT, M.D., Professor of Pediatrics, Northwestern University Medical School; Attending Physician, Michael Reese Hospital, with the collaboration of A. LEVINSON, M.D., Associate Pediatrician, Michael Reese Hospital. **ORTHOPEDIC SURGERY** edited by JOHN RIDLON, A.M., M.D., Professor of Orthopedic Surgery, Northwestern University Medical School, with the collaboration of CHARLES A. PARKER, M.D. Series 1917. Price, \$1.35. Chicago: The Year Book Publishers.

THIS volume of the Practical Medicine Series deals with pediatrics and orthopedic surgery. The part of the book in which infant feeding is discussed is especially interesting. Among other methods for the preservation of milk, reference is made to treatment with hydrogen peroxide. Albumin milk used as a dietetic measure in the treatment of intestinal derangements is also referred to. Several of the diseases to which children and infants are especially subject are considered at length. The section on orthopedic surgery is excellent and the book is fully up to the standard of the other volumes of the series, which is no slight praise.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting Held November 20, 1917.

DR. SAMUEL A. BROWN IN THE CHAIR.

The program of the evening was contributed by the Medical Staff of Mount Sinai Hospital.

Eventration of the Right Half of the Diaphragm.—Dr. EDWARD A. ARONSON made this presentation. He stated that the condition of the diaphragm appreciated as an eventration had been clothed with many synonyms such as dilatation, relaxation, muscular insufficiency, high position, elevation. Others had used these terms to describe a pathological condition of the diaphragm which permitted the abdominal viscera to be displaced upward. In this respect the condition was different from hernia of the diaphragm, which, whether true or false, was dependent on the presence or absence of a hernial sac consisting of a localized opening in the sheet of the diaphragm through which the abdominal viscera passed into the thoracic cavity. All the terms mentioned were partially descriptive though none were satisfactory. Eppinger, in 1911, published a study of 635 cases of true and false hernia and eventration of the diaphragm. Of this series of cases only 17 were eventrations, two being right-sided and 15 left-sided; thus the ratio of eventration to hernia was 1 to 37. This gave a very good idea of the rarity of the eventration of the diaphragm. There was a great preponderance of left-sided hernias and eventrations over those of the right side. Bayne Jones had collected from the literature 45 cases of eventration and described a third case of right-sided eventration. The clinical symptoms and the physical signs of hernia and eventration were not essentially different; the Roentgen examination afforded the most effective means of exact diagnosis and of differentiating the one from the other. In the etiology of the condition, apart from being congenital, it might occur in disease of the motor columns of the cervical cord, as for example, in anterior poliomyelitis, tumors such as tubercle, gummata, lepra tubercles, in diseases of the cervical vertebrae, fracture and dislocation of the mid-cervical vertebrae, involvement of the anterior horns, hemorrhages in the anterior horns, or into the meninges surrounding them, the latter being mostly of traumatic origin. It might also be seen in Duchenne-Erb paralysis, in tumor compression of the phrenics, in tuberculosis caused by compression of the thoracic glands, as a neuritis, in infectious diseases as diphtheria, in alcoholic, lead, chronic arsenical, carbon-dioxide and opium poisoning, in acute and chronic inflammation in the vicinity of the phrenic nerves, as in pleuritis, in progressive muscular atrophy, in tabes, and hysterical and rheumatoid forms have also been described. Dr. Aronson said he wished to add a fourth case of right-sided eventration, which occurred in a young woman, 20 years of age, a Russian, saleswoman, admitted to the hospital on August 22, 1917, and discharged September 21, 1917. Her chief complaint was pain in the right hypochondrium for the past two years. Her family and past history were negative with the exception that she had fallen from a car just prior to the beginning of her complaint. The pain in the right hypochondrium was cramp-like in character, increased by taking food, usually occurring one hour after taking meals and accompanied by nausea and frequent vomiting. The patient also induced vomiting for the relief of epigastric distress and distention. She had frequent eructations, of no particular taste or odor, no jaundice nor hematemesis, was constipated, had frequent attacks of pain at night, frequent headaches, some loss in weight and had had several fainting spells. She had no cardiac, respiratory, or genito-urinary symptoms. The abnormalities revealed by physical examination were anemia, pigmented spots on the abdomen, increased respiration, slight dyspnea at times, and slightly palpable cervical, axillary and epitrochlear nodes. Examination of the lungs showed dulness above the right clavicle, becoming tympanitic below and continuing so to the costal margin. On the left side the pul-

monary resonance was normal. On the right side in the supraclavicular region breathing was rough and loud; below breathing became diminished and finally absent. Posteriorly there was dulness over the suprascapular region with tympany below the shoulders. Over the upper portion breathing was rough and loud; below it gradually diminished. On pressure in the right epigastrium or over the right hypochondrium musical gurgling sounds were heard. On the left side posteriorly there was relative dulness and breathing was somewhat rough. Examination of the abdomen showed resistance in the right hypochondrium. The edge of the spleen could be felt two inches below the costal margin. The heart was displaced, the apex being in the sixth space in the anterior axillary line. Pulse action was increased but of normal tension. The writer presented the data with reference to the examination of the blood, stomach contents, blood pressure, etc. The roentgenographic plates of the chest which he exhibited showed almost complete absence of the lung markings on the right side. At the level of the second rib anteriorly a linear line traversed the chest, the convexity of which was upward. Below this shadow the lung structure was absent and was replaced apparently by air. The linear shadow was probably the diaphragm. The heart and the mediastinum were displaced toward the left. Fluoroscopic examination showed the diaphragm on the right side to be almost motionless on respiration. Examination of the colon after the injection of a barium enema showed a markedly distended colon. The megacolon was so marked that it pushed the right side of the diaphragm up to a high point in the thorax. This patient had been operated upon last Saturday by Dr. A. A. Berg and when the incision was made the colon was so large that it immediately extruded itself through the incision. He resected three feet of the colon and made a side to side anastomosis. While the very large colon was pushing the diaphragm up he did not believe that this alone was the cause of the eventration, but that there must have been in addition some pathological condition of the diaphragm which permitted the eventration, though just what this condition was they had not yet determined.

Dr. ALFRED MEYER said that he had heard of this case which Dr. Aronson had just reported, and while the malposition and the high position of the diaphragm were interesting, a point to which he wished to call attention was the paradoxical excursions of the diaphragm sometimes, though not frequently, observed in artificial pneumothorax. In these exceptional cases the diaphragm *ascended on inspiration* on the side of the artificial pneumothorax in place of descending. That was perhaps because of the paralysis of the diaphragm on that side. The conditions of intraabdominal pressure were such that during the excursion of that portion of the diaphragm which was functioning the viscera were pressed down and in consequence of this an upward pressure would be exerted on the side of the artificial pneumothorax. He mentioned this because he thought the phenomenon bore a certain relationship to that of the case reported, though there was admittedly in both some difference of opinion in regard to the exact explanation.

Dr. L. T. LEWALD said he had three cases of bilateral eventration, all occurring in males, and he had been struck, just as Dr. Aronson had been, by the apparent upward displacement of the diaphragm of the colon. In his cases the displacement was not to quite such a high point on the right side as in the case reported by Dr. Aronson; on the left side the displacement in all of the cases extended up to about the third rib. These three cases all occurred in males, two of them being only seven or eight years of age, and the third an adult, so that he felt that the condition was distinctly a congenital one and associated with a malposition of the diaphragm due to the enlarged colon. He did not think the condition was due to a paralysis of the diaphragm.

Dr. MAURICE FISHBERG called attention to an elevation of the diaphragm sometimes observed in tuberculosis. They occasionally found a case in which the liver was up to the third or fourth rib and the diaphragm might be high on both sides, especially in cases of pleuritis. Again one might have fibrous bands formed as the result of tuberculosis which would push the viscera downward. The elevation of the diaphragm

in tuberculosis had always struck him as rather peculiar and he had been inclined to attribute it to a paralysis or irritation of the phrenic nerves. This case of Dr. Aronson's was simply a case in which there was a higher degree of elevation than that due to tuberculosis.

Dr. ARONSON, in closing, said that there was one point to which he had called attention and that was that the patient's symptoms began just after a fall from a car. He did not want to dispute the statement that the megacolon was of congenital origin, but the fact was that the patient only began to have symptoms since just after the fall and the question arose whether the fall had occasioned an injury to the mid-cervical vertebræ causing paralysis of the nerves, so that the possibility of the fall having been an exciting cause of the eventration was an open question. He believed there was a prior pathological condition of the diaphragm which permitted the megacolon to push it up, so that the eventration was the result of the association of both conditions.

A Case of Artificial Pneumocardium.—Dr. ALFRED MEYER made this contribution. He stated that injections of air, oxygen, or nitrogen, into serous cavities for the relief of various diseases had been advocated for many years. He reviewed some of the instances reported in the literature in which procedures of this kind had been applied in tuberculous peritonitis and cirrhosis of the liver. The procedure, as was well known, had found its most extensive application in pulmonary tuberculosis. The pericardium appeared to be in respect to gas introduction an untilled field. The only two cases which the writer had been able to find in the literature of the therapeutic introduction of gas into the pericardial sac were those of Wenckebach (*Ztsch. f. klin. Med.*, '10, Vol. LXXI, 402) and that of Weil and Loiseleur (*Prose Médicale*, Dec. 28, 1916). These cases Dr. Meyer reported in detail in view of the rarity of the procedure. His own case, probably the third reported in the literature of this subject, was admitted to his service at Mount Sinai Hospital on April 26, 1917. The patient was a woman, 20 years of age, married 14 months, and the mother of a child five months old. Her past history showed that she had had an appendectomy four years ago. The onset of her present trouble occurred four months before admission to the hospital, with cough, fever, shortness of breath, and later occasional vomiting and precordial distress. Before her admission to Mount Sinai Hospital she had been in the New Haven Hospital where she had been aspirated several times and where the diagnosis of polyserositis was made. On May 1, 1917, the writer aspirated the pericardium, removing 1350 c.c. of bloody fluid and introducing 180 c.c. of nitrogen gas. The gas injection was made under local anesthesia with the Floyd Robinson apparatus. There appeared immediately distinct succussion at the first left interspace near the sternoclavicular junction and at the level of the spine of the left scapula, but at no time was there a splash with cardiac systole. The extreme width of precordial dullness before aspiration was 24 cm.; after aspiration the exact limits were determined with difficulty on account of the admixture of tympany, but there was a reduction of at least three or four cm. The heart sounds were more plainly audible. The radiographic report of May 4 showed a condition of hydro-pneumopericardium. The heart border extended on the left side as far as the axillary line, and on the right side almost to the mid-clavicular line. The pericardium was almost completely filled with fluid, the fluid level extending as far as the level of the third rib anteriorly. Above the level of the fluid the pericardium was distended by an accumulation of air. By May 10 the fluid had gradually reaccumulated and there was no longer any evidence of air in the pericardium. The pericardium was again tapped on May 10, 1270 c.c. of bloody fluid being withdrawn; no nitrogen was substituted. Four more aspirations were done between this time and June 7. On June 7, 700 c.c. were withdrawn and 650 c.c. nitrogen injected. In the meantime the ascites had increased to such an extent that a paracentesis abdominis was made on June 12 by Dr. H. W. Berg, 2120 c.c. of clear straw-colored fluid being removed. After emptying the abdomen, the sharp edge of the lower border of the liver apparently much enlarged was palpable. On June 26 and July 14 paracentesis abdominis was

again performed. During this period general anasarca was continually on the increase, but there was no necessity of tapping the pericardium until July 24, one month and 17 days since the substitution of nitrogen. During all this time no positive conclusion as to the underlying cause of the patient's trouble was reached. She had occasional slight fever, never above 102, mostly between 99 and 101, and during the last three weeks of her stay mostly subnormal. Her blood pressure was always low, but there was a high hemoglobin and red cell count and a leucopenia. The urine had occasional albumin and occasional hyaline and granular casts. The Wassermann was negative and the pericardial fluid was negative for tuberculosis. The ascitic fluid was also negative. This patient left the hospital, on July 28, and died probably two or three weeks later. As yet he had been unable to ascertain whether an autopsy had been performed. The weight of evidence seemed to favor the conclusion that there was some central circulatory disturbance involving perhaps a partial closure of the vena cavæ. Dr. Meyer said he was reporting the case for the purpose of accentuating the simplicity and safety of this procedure in cases of pericardial effusion which required tapping. He would certainly urge its trial in cases of tuberculous pericardial effusion, in view of the experience in cases of tuberculous peritonitis and in the two cases quoted from the German and French literature. From a study of his case (non-tuberculous though it was) it would appear reasonable to introduce larger proportionate amounts of gas than were employed by him at the original tapping. A natural conservatism in view of the newness of the procedure guided him at the time of the first substitution, but at the last tapping nearly as much gas was introduced as fluid had been removed (750 c.c. and 650 c.c.), and this with perfect comfort to the patient. In a proven tuberculous pericardial effusion, Dr. Meyer stated that if the occasion arose in the future, he would use oxygen or possibly ozone gas. During the study of this case it had occurred to him that a similar procedure might possibly be of service in cases of hydrocele and he had suggested it to some surgeons for trial. Even in diseases of the cerebrospinal canal there might be a future for this procedure.

Dr. LOUIS HAUSWIRTH said that the injection of air into the peritoneal cavity after tapping, to which Dr. Meyer had referred, had been made for diagnostic rather than for therapeutic purposes. A German observer had been able to gain some information with reference to the condition of the spleen and liver by the use of the oxygen injection. He injected oxygen until the splenic dullness disappeared entirely, and then the fluoroscopic and radiographic examination showed that the diaphragm was lifted far off of the kidney and liver and the outlines of the kidney and liver were shown very distinctly. Such a procedure as this might be of value in the diagnosis of abdominal tumors. So far as the therapeutic effects were concerned they were not very successful in this case. With reference to the length of time that the air or gas remained in a closed cavity it seemed that in ascites it escaped very quickly through the trocar, and it seemed to have no influence on the reaccumulation of fluid. He had tried Dr. Fishberg's suggestion that gas replacement might be employed in pleurisy; in his hands it had been a dismal failure. It seemed that oxygen would be absorbed in about twenty-four hours and nitrogen in three or four days after intraperitoneal injection. In one patient who had repeated hemorrhages from the lungs he had considered the advisability of producing artificial pneumothorax, and had made two or three attempts, but found that pleural adhesions made the procedure impossible. A member of the house staff, not knowing of his attempt, tried to make an injection into the eighth or ninth interspace and went into the peritoneal cavity. No harm resulted. All those doing artificial pneumothorax understood that if they entered the pleural cavity the manometer gave a negative pressure reading, and that if they entered the peritoneal cavity the reading would be positive. The diaphragm was often quite high in cases of tuberculosis, even as high as the second, third, or fourth rib. Perhaps Dr. Meyer's procedure might work well in cases of pericardial effusion, but it had not been successful thus far in cases of pleural effusion or ascites.

Dr. MEYER, in closing, said he could also report a case

which occurred in the practice of a colleague in which the peritoneal cavity was entered in the attempt to enter the thoracic cavity. So far as they could judge from their limited experience with this procedure it was valueless in cirrhosis hepatitis. So far as the relative value of nitrogen and oxygen was concerned the oxygen was absorbed more quickly, at any rate in the pleural cavity. Ordinarily, therefore, in making a substitution nitrogen gas was certainly preferable to oxygen. Dr. Meyer said he had also made substitutionappings in cases of hemothorax in several cases of malignant disease of the lung and pleura and in one case of leucemia, using nitrogen. The final outcome of course was not satisfactory, but he felt that the final outcome of cases of tuberculous peritonitis was so hopeless that they were justified in making every possible attempt that gave promise of relief along the lines he had described, and that the limited experience thus far on record seemed to justify artificial pneumopericardium. In all such cases as these, Dr. Meyer said, atmospheric air or oxygen should be used.

A Case of Polycythemia with Focal Nervous Symptoms.—Dr. LOUIS HAUSWIRTH reported this case for Dr. MORRIS MANGES. He stated that his reason for making this report was because Dr. Christian had recently reported ten cases of polycythemia, seven of which presented symptoms of profound nervous disturbance. It had been his impression that only about 30 per cent. of these cases of polycythemia presented marked nervous symptoms of a focal character. The case he reported was that of a woman forty-eight years of age, who always lay on her left side and whose spleen was markedly enlarged, extending beyond the umbilicus. She had attacks of a neurotic nature localized in the right eye. The pain in the right eye radiated to the back of the head. The patient also complained of pain in the right forearm and hand and weakness and numbness of the forearm and hand. All of her pain and symptoms were relieved when she was lying down. She had the characteristic cherry-red spot in the eye. The blood examination showed 9,150,000 red blood cells and 135 per cent. hemoglobin. The findings of the blood examination were somewhat different from those of Dr. Christian. The speaker compared the findings of Dr. Christian and Dr. Lucas in respect to the blood examination in polycythemia and commented on the fact that Dr. Lucas had found nervous symptoms present in only 30 or 40 per cent. of his cases.

A Case of Large Pericardial Effusion.—Dr. HAUSWIRTH reported this case also for Dr. MANGES. He stated that the patient was a young man twenty-eight years of age with an enormous pericardial effusion apparently due to a rheumatic condition. The question was whether one should tap such cases. In cases which one decided to aspirate an x-ray examination should be made first in order to be sure that in making the aspiration they were entering the pericardial cavity.

Dr. GEDIDE A. FRIEDMAN said that during the past few years he had had three cases of polycythemia vera, one of which he had published. In all of these cases he had observed nervous symptoms, and these he thought could be attributed rather to irritation of the sympathetic nerves than to the vagus. He also described polycythemia occurring frequently in patients suffering from chronic duodenal ulcer. In patients suffering from chronic gastric ulcer there was usually a mild anemia. Practically all of these duodenal ulcer cases with polycythemia presented nervous systems which one would call stigmata of the vegetative nervous system. However, the symptoms and signs correspond rather to sympathicotonia. He had been experimenting on dogs and rabbits with adrenalin. When he injected the usual dose of adrenalin and then took the blood count he found that the red cell count was markedly increased. In one dog two hours after the adrenalin injection the erythrocytes rose from five to eleven millions in the c.c. of blood; in other words an excess of adrenalin in the system caused a polycythemia. From these findings it might be argued that polycythemia might have some relationship to a disturbance of the glands of internal secretion. Dr. Friedman said he had also injected dogs with glandular secretions and had produced acute duodenal ulcers with adrenalin. This work was published in the *Journal of Medical Research* in 1915. Taking all these facts into consideration it seemed possible that

there might be a relation between polycythemia and an excess of adrenalin.

Dr. ROSENBLUTH recalled two cases of polycythemia coming under his observation, one of which showed symptoms of hemiparesis due to an exudate in the brain, and the other a patient who was neurasthenic and showed symptoms referable to the vegetative nervous system.

Dr. ALFRED MEYER said he just recalled that in looking through the literature of pericardial effusion and its treatment he had come across the treatment of tuberculous effusion by aspiration and the injection of a gram of naphtholated camphor. It resulted in a cure, but with total adhesion. The pulse rate first rose from 120 to 180 and the patient had attacks of syncope. The case seemed to show, Dr. Meyer said, how nature sometimes protected the physician against disaster that he seemed to have invited.

Dr. HAUSWIRTH said he did not think Dr. Friedman's theory as to the relation between polycythemia and the sympathetic nervous system could be substantiated. Dr. Christian had called attention to the fact that the condition was definitely associated with lesions in the blood vessels and that it was perfectly possible for these lesions to be transitory; they might subside and the patient recover. The point to be emphasized was that nervous symptoms should lead the physician to make a blood count to see whether or not the disturbance of the sympathetic nervous system might not have its basis in a polycythemia. He felt sure that if physicians were stimulated to look more carefully for these cases they would find polycythemia of more frequent occurrence than they had hitherto believed.

Multiple Hydatid Cysts of the Liver.—Drs. A. V. MOSCHOWITZ and A. O. WILINSKY presented this patient, a Greek, thirty years of age, who was admitted to Mount Sinai Hospital on August 8, 1917. Dr. Wilinsky stated that the patient had complained of masses in the abdomen for two weeks before admission. The family and personal history were negative. The patient had lived in Greece until nineteen months ago. He then was in Paris for six months and had been in New York thirteen months. The patient, aside from the increasing size of the mass in his abdomen, felt well. Physical examination showed the submaxillary, axillary, and inguinal glands palpable. Examination of the lungs showed numerous moist râles at the right base posteriorly. There were three prominences in the upper half of the abdomen which moved with respiration. These masses felt cystic. On percussion there was a distinct thrill imparted to the finger. Rectal examination revealed high up in the midline a sense of resistance and slight tenderness. Dr. Moschowitz performed an operation which consisted in a marsupialization of the echinococcus cysts of the liver. He found a large cyst in the left lobe of the liver on the upper surface, a smaller cyst below the margin of the left lobe, and one under the right lobe in the flank. Part of the lining of the lower cyst was excised. The lining of the cysts of the left lobe was then swabbed with 10 per cent. formalin. The cyst in the right lobe was not attacked because of its inaccessibility and the poor condition of the patient. For three weeks after the operation there continued to be a discharge of bile-stained fluid with cysts and liver debris. Because of a daily rise in temperature a second operation was performed, at which one large cyst on the under surface of the right lobe and another on the upper surface of the right lobe were incised and marsupialized as before. The cyst on the upper surface contained a large amount of pus and the cavity extended up under the diaphragm. The incision in the right rectus was closed in layers and the patient made a good recovery. Owing to the profuse loss of bile the patient had been given bile. He was still discharging a moderate amount of light-brown material with daughter cysts. It seemed quite probable that he would have another operation.

Dr. MOSCHOWITZ said he had had occasion within a few days to see the brother of this patient and he was able to supply a missing link in the history. He had questioned this brother as to whether the patient had ever had a dog or tended sheep. The brother said the disease was very common in Greece and he had seen sheep killed in which they had found something that looked just like the daughter cysts which which had been removed from the patient.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 27, 1917.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Large Pedunculated Cavernous Angioma of the Liver Reaching into the Pelvis and Causing Obstetric Difficulty.—Dr. I. C. RUBIN reported this case and exhibited the specimen. He said that this cavernous angioma of the liver which he had recently removed was unique both from the point of view of its large size and the serious difficulty it caused during pregnancy. The patient was a young woman, 33 years of age, who had already born 12 children, eight of whom were twin pregnancies. During her last gestation her abdomen had increased so markedly in size that she considered herself again pregnant with twins. The abnormally large size of the abdomen with increasing sense of discomfort and then pain led to an induction of premature labor. The presence of the abdominal tumor then became obvious. The diagnosis of ovarian tumor was made because of the location of the tumor in the abdomen and the palpatory findings on bimanual examination. On laparotomy it proved to be a giant sized pedunculated cavernous angioma of the liver. It was easily removed without hemorrhage. Recovery was complete and uneventful. In regard to the diagnosis, it seemed that if they had paid sufficient attention to the percussion signs, namely, dullness in the right hypochondrium continuous with the liver dullness, they might have ascribed the origin of the tumor correctly to the liver and not to the ovary. However, the great rarity of tumors of this variety and the greater frequency of ovarian tumors complicating pregnancy would favor the latter as the most probable diagnosis. Apparently laparotomy alone could establish the diagnosis in this as in many other instances of large abdominal tumors. The specimen removed was ovoid in shape, measured 24 by 16 by 4 inches, and weighed four pounds and twelve ounces. On section it resembled liver tissue with peculiar myxomatous changes. There were several circumscribed areas about the size of a silver half-dollar which were pale and homogeneous in color and suggested possible malignant changes; these, however, on microscopical examination proved to be fibroid changes, while the great mass of the tumor proved to be a cavernous angioma.

A Case of Twin Pregnancy; One Child a Monster.—Dr. GEORGE W. KOSMAK reported this case. He said the subject of twin pregnancy was of interest both from the biological and obstetrical standpoints. Considerable difference of opinion existed as to how twin pregnancies developed in the unioval variety, but they did know that they were generally of the same sex and that there was an anastomosis between the two vascular systems in the placenta which was not present in the fused placenta of double ovum twins. Occasionally one fetus was so much larger and stronger than the other that it crowded the second fetus to such an extent that the latter became flattened out and assumed the character of a fetus papyraceus. In other instances the heart of one embryo was so much stronger than that of the other that it monopolized the gradually increasing area of the common placenta. As the other fetus received less and less blood it failed to develop, and a mere remnant was left to which the name of acardia was given. Then again they sometimes had a hydramnios in the case of the larger fetus, supposedly due to the fact that the stronger heart appropriated the largest share of the blood with a corresponding hypertrophy of the kidney function. In the case reported variations to these general rules were to be seen. Although the first fetus was normal and larger than the second, the contents of its amniotic sac were quite normal in amount; whereas the smaller and abnormal fetus developed in an amniotic sac that contained at least a gallon of fluid at the time of delivery. Although evidently of bioval origin, both twins were of the same sex. Another feature of interest in this connection was that in this type of twin pregnancy no anastomosis between the placenta could have been present. For this reason also the second twin could not have been interfered with by the growth of the first. In none of the obstetrical text-books which were

consulted was any record of a similar anomaly found. The patient was 35 years of age, a IV-para, who was admitted to the Lying-in Hospital on October 13, 1917. At the time of admission the cord was found prolapsed, the cervix four fingers dilated and the vertex presenting. A version and breech extraction was done and a normal baby, weighing 2200 grams, was delivered. The abdomen remained greatly distended, and as there seemed no reason for waiting, the membranes were ruptured and a large amount of liquor amnii allowed to escape. The second fetus presented by the breech and was easily extracted. It was an anencephalic monster, weighing 1420 grams, and died about an hour after birth. An examination of the secundines showed two distinct placenta and sacs. There were no abnormalities in the placenta. The sex was the same in both fetuses. The mother and baby were discharged in good condition.

Tyramine in Labor.—Dr. ALFRED M. HELLMAN presented this report. He said that his interest in tyramine as an adjunct in labor had been aroused by the statements of Professor Barbour of the Department of Pharmacology of Yale University. Through the kindness of the manufacturers he had secured sufficient tyramine for nine doses and administered it during October to nine patients on the service of Dr. Seeligmann at Lebanon Hospital. Eight times it was given with morphine when this latter drug was indicated, the dosage being that suggested by Barbour, namely, 16 mg. of morphine sulphate given hypodermically in solution with 40 mg. of tyramine. Tyramine was a synthetic preparation, parahydroxyphenylethylamine hydrochloride. Laboratory workers had called attention to it as a respiratory stimulant and others had noticed that it counteracted the respiratory depression of morphine. It was claimed that experimentally it caused a rise in blood pressure which was more gradual, lasted longer, and was less powerful than adrenalin, but resembled this drug. In 1910 Dale and Dixon from some experiments deduced that besides its adrenalin action it caused in rabbits contractions of the uterus and vagina, more marked if the animals were pregnant, but it did not bring on labor. Its oxytocic action was also noted by Guggenheim, whereas Lieb called attention to the fact that it stimulated the sympathetic nervous system and that it also stimulated the non-pregnant as well as the pregnant excised human uterine muscular tissue. Judging from a review of the literature, one would have expected to find that the use of tyramine in labor would increase the mother's respirations, raise blood pressure, that the analgesic effect of morphine would be unaltered, and the uterine contractions stimulated until the end of labor. Unfortunately, his own experience did not bear out these reports. In the eight cases in which the drug was used the respirations of the mother were unchanged and the blood pressure was lowered from 5 to 15 mm. of mercury in six cases; in one there was no change, and in the other there was a five-point increase. In every case the pains became decidedly less frequent and seemingly less powerful. Dr. Hellman said he realized that the cases were not enough to allow a definite conclusion, but to him the results were quite a surprise and were not very satisfactory.

The Rationale of Radiotherapy in Uterine Hemorrhage.—Dr. JAMES A. CORSCADEN presented this communication, in which he first drew attention to the gradually prevailing view, as expressed in an extensive literature, that abnormal uterine bleeding formerly attributed to anatomical lesions, such as chronic endometritis, fibrosis of the uterus, arteriosclerosis of uterine vessels, syphilis and tuberculosis of the uterus, chronic passive congestion of local origin, etc., was due to extrauterine agencies, alterations in the menstrual mechanism, to correct which we must attack some link in the menstrual cycle, particularly destruction of either the corpus luteum or the endometrium. In summarizing the effect of the use of radiotherapy on the grossly normal uterus he stated that radiant energy exerted a specific destructive effect on the Graafian follicle. Menstruation was dependent on and controlled by a corpus luteum formation. Destruction of the Graafian follicle must therefore cause an amenorrhea. The majority of abnormal uterine hemorrhages were due to disturb-

ance in the menstrual mechanism, and not to local mechanical causes, therefore these bleedings must cease in the same manner as normal menstruation, under radiotherapy. Added to its effect on the corpus luteum, radium had a local cauterizing effect on the uterine cavity. In women of the late child-bearing period radium was the procedure of choice. In girls radiotherapy should be used as a late procedure. The speaker then discussed the position of radiotherapy in the treatment of hemorrhage associated with fibromyomata, summing up his ideas as follows: (1) Results showed that amenorrhea followed radiotherapy in fibromyoma of the uterus precisely as it did in uterine bleeding with any other benign condition. (2) Following radiotherapy the mass shrank to a marked degree, often so much as to escape the examining finger. (3) Fibromyomata should remain untreated unless they caused symptoms. (4) When the symptom to be treated was hemorrhage, radiotherapy was the treatment par excellence, because it put the condition again in the symptomless class. (5) Since amenorrhea should be permanent, radiotherapy was best indicated in women of thirty-eight or over and restricted more and more as the ages were lower. (6) Where mechanical symptoms predominated they were best treated mechanically, that was by operation. Carcinoma was practically out of the scope of this paper, since the hemorrhage of carcinoma, although important, was of small importance compared with the other dangers of the disease; nevertheless allusion should be made to its treatment by radiotherapy. In a small number of cases of inoperable carcinoma coming under his observation in which more or less severe bleeding had been a symptom, it had been controlled, and the immediate results were like those reported from many sources. His experience with inoperable carcinomata of the cervix showed that treatment by radiotherapy was just as rapid and just as complete as when treated by the Percy method. Thus far no accidents had followed the use of radium. Dr. Corscaden stated that the series of cases from which he had drawn his deductions included 44 cases in women of 38 years of age or over treated by the x-ray; eight cases in women under 25 years of age treated by the x-ray; four cases in women of from 30 to 35 years treated by the x-ray. There were nine cases in women over 38 treated by radium; one case in a woman of 31 treated by radium. Among the women of 38 or over there were 22 cases with fibromyoma; among the women between 30 and 35 years there were two cases of fibromyoma. In the women of 38 or over treated by x-ray, menstruation ceased after the treatment, and there was no further bleeding in one case, no further bleeding after one period in 12 cases; there was no further bleeding after intermittent dribbling lasting for several weeks in three cases. In one obese subject scant menstruation coincident with hot flushes continued for four months after x-ray treatment and was stopped completely after an application of radium. The uterine bleeding in eight girls had been controlled with varying success in all cases. In three of them something approaching a regular menstrual period was accomplished. In the other five varying periods of amenorrhea were induced. The results of the cases treated by radium were too recent to be suitable for tabulation. In general it might be said that amenorrhea occurred after one period. The profuse first period following the x-ray treatment had only a mild counterpart after the radium installation. The secondary results of x-ray treatment had practically stimulated the normal menopause. There had been a few gains in weight, but no adipose. The only characteristic symptom of the menopause had been the onset of hot flushes; this had been serious in one case; absent in two, and moderate in the rest of the women of 38 years or over; it had been severe in one young woman, absent in four, and moderate in the rest. Comparing the x-ray and radium, it might be said that radium was preferable in practically all cases except young women, in whom small repeated doses might be desired. While the actual time consumed in the treatment was about the same for both, that devoted to x-ray was spread over from six to ten weeks, while the radium was finished in twenty-four hours. In conclusion it might be said that uterine hemorrhage from almost any cause might be stopped by the intra-

uterine application of radium, and that the hemorrhage from disturbed menstruation with or without fibromyoma might be controlled by the x-ray. Also practically all fibromyomata would shrink to a satisfactory degree after radiotherapy. All cases of hemorrhage from a grossly normal uterus in a woman of 38 years or over should be treated by radiotherapy after carcinoma had been ruled out. In younger women radiotherapy should be used as a late resort.

Dr. S. STERN said that he had treated in hospital and private practice several hundred cases of hemorrhage and fibroids by radiotherapy, the patients ranging in age from 14 to 60 years. The results had been just as Dr. Corscaden had said; there was absolutely no question that we could induce an amenorrhea in any patient if a sufficiently large dose were given. He had had a number of cases in young women in which amenorrhea followed the treatment, lasting up to two years, and then menstruation began again. In some instances these women had become pregnant and had borne perfectly healthy babies, and they were perfectly healthy to-day and had had no recurrence of the fibroid or of the hemorrhage. The only difficulty with this treatment was to know how to gauge the dosage. He had no doubt the time would come when we would be able to work out a definite formula and by following this get identical results. There was no question that one occasionally got young girls who should be treated radiotherapeutically. Dr. Stern said he had never seen a case under thirty years of age that did not menstruate again. In the older women the question of dosage depended upon how near the menopause they were. As to the interesting question of how the radiotherapy did the work, at one time it was thought that the results were obtained entirely through the reflex action produced on the ovaries, but he was inclined to think there was a decided action on the fibroid tissue itself. The fact that one obtained this effect upon a fibroid in a woman long past the menopause in whom the ovaries were atrophied would suggest that the effect was produced in some other way than only through the ovaries. There were not many contraindications to this treatment if one could rule out malignancy. This was sometimes very difficult, and it might happen that some mistakes might be made. Of the 300 or more cases coming under the speaker's observation there was only one which proved later to be carcinoma, and in this case there was some suspicion of malignancy from the beginning. He did not know why Dr. Corscaden took the age of thirty-eight years and said that when the patient was under thirty-eight years he preferred a surgical procedure. He believed that if an operation could be performed in such a way that enough of the uterine organ could be preserved to keep up menstruation it was probably better than to take a chance of making the woman permanently amenorrheic. But otherwise he thought that radiotherapy which was likely to produce only a temporary amenorrhea was better than a procedure which surely made the patient permanently amenorrheic.

Dr. L. T. LEWALD said the findings of Dr. Corscaden were in agreement with those of Dr. Pfahler, and he was inclined to believe his rationale was correct. His selection of cases followed that of Dr. Pfahler and others who were doing successful work along this line.

Dr. HOWARD C. TAYLOR said there was little in which he would not agree in what Dr. Corscaden had said. He wished that Dr. Corscaden had said more about the dosage. The literature contained much regarding the results of the use of radium, but little regarding the exact dosage, amount of filtration, and the duration of the application. The vast majority of cases of uterine hemorrhage could be cured by curettage. If one took all those due to metritis, retroversion, fibroid, or conditions of the appendages, he usually preferred to do a curettage and such other operation as might be indicated rather than use radium or the x-ray. If a young girl flowed profusely, and no real lesion was found in the pelvis, it was his custom to regulate her life, her exercise, rest, and general hygiene. He disliked to curette a young girl, but would curette her rather than use radium, though he certainly would use radium before he would do a hysterectomy. He would not use radium until a curettage had failed more than once. In the treatment of fibroids he thought it was

not a question of whether a woman was 38 or 44 years of age, but whether she needed her uterus or not. A woman might be 40 or 41 years of age and just married and in that case she did not wish to remain sterile. On the other hand, if a woman was under 38 years of age and had children and did not care to have any more, she had less need for her uterus and it was of less importance to save it. Myectomy seemed preferable if the woman needed her uterus and wanted a chance to have children. One could do quite an extensive myectomy with safety without rendering the woman sterile. Dr. Taylor said he wished Dr. Corascaden would make some reference to his treatment of submucous fibroids.

Dr. HIRAN N. VINEBERG said he thought Dr. Corascaden had given a very fair presentation of this subject and had furnished a standard upon which we could look as a guide in the future in our own cases. He thought Dr. Taylor had struck the keynote. If one started out to do a myectomy, it was surprising how few cases there were in which one could not do this operation, and in this way a great many uteri could be saved. As to the submucous fibroids, those who had operated on this kind of growths knew how easily one could shell them out. He had had very little experience with radium or the x-ray, but he thought every gynecologist should be familiar with these methods of treatment and should avail himself of them in some cases. As to the young girls, he had had one case in a young girl who had been curetted several times and this procedure had failed to control the hemorrhage. She was in a desperate condition and it was imperative that something be done. He decided to open the abdomen, and upon doing so found that one ovary was double the normal size. He simply incised this ovary. It was now nine months since this had been done and the patient had had no more hemorrhage and was in normal health.

Dr. HERMANN GRAD said he thought the paper was fair and very instructive. He had had three experiences with cases that had come back from the radiologist after they had been treated. These cases were of three distinct types. The first patient was a woman treated for uterine hemorrhage for four months who was sent back because the radiologist feared malignancy. Although there was nothing demonstrable on microscopical examination of the curettings, hysterectomy was done. The specimen showed a fibrosis of the uterus and an extremely marked endarteritis. In the myometrium there were very peculiar changes which the pathologist said he had never seen before, and there appeared to be a great deal of scar tissue. The ovarian structures also showed changes under the microscope; one could not demonstrate a Graafian follicle at all. In this case the x-ray treatments did not control the bleeding. In another case, a young woman treated for about six weeks, the hemorrhage was not controlled. The woman had been treated for fibroids, but on opening the abdomen it was found that she had a pyosalpinx on both sides and no fibroid. This brought up the question of diagnosis; differential diagnosis was difficult at times. In another case of submucous polyp the hemorrhage was not controlled by the x-ray, though there had been a sufficient number of exposures to have produced such an effect. At operation a polyp was found; here again was the question of diagnosis.

Dr. HARRY ARANOW said his experience had been just the opposite of that of Dr. Grad. He cited several instances in which x-ray and radium had been effective when other measures failed. He said he had the impression that in women around the age of 38 or 40 years the x-ray was more effective than in younger women in controlling hemorrhage due to fibroids.

Dr. CORSCADEN, in closing, said he had simply taken the age of 38 years because it represented about the average of a number of cases taken from the literature. It was about the age at which the conditions laid down by Dr. Taylor more often occurred, and it was the age at which the majority of women ceased to want to have children. His original reason for selecting this age was that after this time one did not need to have much fear on account of menopause symptoms. He had seen these symptoms of the menopause in young girls and found that they were largely psychic. As to the dosage

and what was meant by a massive dose. A massive dose of x-ray was this: The abdomen was divided into ten areas and each area was given an erythematous dose, that was a dose just short of what would burn the skin, and this dose was repeated as quickly as was convenient. Then a second similar series of doses was given three weeks later, and a third again three weeks after this. No one really knew what a massive dose of radium was for a case of metrorrhagia or menorrhagia. A limit had not yet been set to the dose in carcinoma. More than 3600 milligram hours was likely to produce a fistula formation. He had put in 25 milligrams for 24 hours, 50 milligrams for 12 hours, and 50 milligrams for 24 hours, and in each instance the result had been about the same, except when one put in 50 milligrams for 24 hours the primary period was less profuse, but there were the same number of periods and the amenorrhea was just as complete. As to the measurement of the fibroids, that was done by the ordinary obstetrical calipers with one straight arm. A discount was made for the thickness of the abdominal wall, and the same discount was made at each subsequent examination. Dr. Corascaden said that in failures to get results with the x-ray treatment he would like to see the apparatus and all the measurements of the x-ray dose. Giving x-ray was like giving digitalis, we must know the proper method of administering it. If one did not know all the factors bearing on the x-ray dose, it was just as useless to attempt to employ it as it was to give a man a handful of strychnine tablets and tell him to use them when he felt he needed them. It was the speaker's custom to do a preliminary curettage and then if a fibroid was present he learned what condition obtained in the cavity, and if he thought operative interference was indicated because of a polyp or pedunculated fibroid he operated, so in a way he was working on both sides of this question.

Dr. TAYLOR asked whether, if several fibroids were found projecting into the uterine cavity, Dr. Corascaden gave radium treatment and whether he had found that radium caused submucous fibroids to disappear.

Dr. CORSCADEN said he gave radium and the fibroids disappeared. He believed the disappearance was due to the effect of the radium on the ovary. He found that under radium treatment these fibroids shrank faster than those that went through the natural menopause.

Dr. HOWARD LINDEMAN said that in their earlier treatment of fibromyoma they used to castrate in order to cure the patient. Some fibroids did diminish in size under this treatment, but many others did not, and it was this fact that suggested to his mind the possibility that the x-ray and radium had some direct effect on the fibroid itself and did not exert their action merely through their effect on the ovary.

Dr. CORSCADEN said he was glad of the opportunity to answer that question. Gaus, Kroenig, Albers, and Shoenberg, and indeed all the German authorities on this subject, agreed that the cases in which there had been a failure to reduce the fibroid after radiotherapy had been those in which menstruation had recurred, and therefore they insisted that in order to make the fibroid disappear menstruation must cease.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE MEDICAL EXAMINING BOARD.

June, 1917.

(Continued from page 1101.)

SURGERY.

1. What is meant by hyperthyroidism and hypothyroidism?
2. Differentiate tuberculous peritonitis and typhoid fever.
3. Mention some of the dangers from the use of spinal anesthesia.
4. Differentiate between contusion and concussion of the brain.
5. Give diagnosis of congenital pyloric stenosis and state what operations will relieve the condition.

6. Differentiate subluxation of the elbow joint and supracondyloid fracture of the humerus.

GYNECOLOGY.

1. Give causes, symptoms and diagnosis of acute cervical atresia.
2. Give symptoms and diagnosis of ectopic pregnancy.
3. Differentiate acute appendicitis, right urethral calculus, and acute salpingitis.
4. Give surgical technique for abdominal hysterectomy.

MEDICAL JURISPRUDENCE, HYGIENE, AND PREVENTIVE MEDICINE.

1. What do civil and criminal responsibility imply?
2. Define: (1) Insanity, (2) Melancholia, (3) Dementia, (4) Paranoia, (5) Idiocy.
3. What is rigor mortis? Why is its rapid appearance of greater medicolegal interest than delayed onset?
4. What is the legal status of a medical examiner in regard to the life insurance company for which he examines?
5. What are the natural purifiers of the atmosphere which prevent its composition from varying much from the normal for any great length of time?
6. Name some of the most important and fatal diseases among soldiers and state the precautions necessary in locating camps and their hygienic management.
7. What are the respective merits of sulphur and formaldehyde as germicides and insecticides?
8. What three measures are necessary in the prophylaxis of smallpox? How long after vaccination before immunity appears?
9. What knowledge is necessary for success in the suppression of an epidemic?
10. The record of what important events are included in the registration of vital statistics? From a sanitary point of view, what is the most important object of a registration of vital statistics?

ANSWERS.

SURGERY.

1. *Hypothyroidism* is the name given to the symptom complex found when the thyroid gland is absent, degenerated, atrophied, or is functionally deficient. There is arrested growth, dry and swollen skin, pale and puffy face, swollen abdomen, hair thin and with a tendency to fall out, weak muscles, the nervous system seems undeveloped, mental dullness, lowered body temperature, diminished sexual activity, lower sensibility, and accumulation of adipose tissue.

Hyperthyroidism is due to an increase of thyroid secretion; there will be noticed lowered blood pressure, rapid pulse, excessive perspiration, nervous excitability, digestive disturbances, loss of fat, and in extreme cases exophthalmus, dilatation of pupils, sleeplessness, and tremors.

2. *Tuberculous peritonitis* is characterized by a distended or retracted abdomen, irregular fever and more or less pain of a sharp character. Occasionally there is diarrhea, sometimes constipation. If the abdomen is distended the presence of free liquid in the abdominal cavity can usually be diagnosed by dullness in the flank and the presence of a wave transmitted from one side of the abdomen to the other when the center line of the abdomen is strongly depressed by the edge of the hand. Occasionally dull areas may be distinguished in various parts of the abdominal cavity.

In *typhoid fever* there are rose spots, enlarged spleen, the peculiar tongue, diarrhea, and the Widal reaction. Typhoid fever is usually more acute than tuberculous peritonitis.—(From Fussell's *Differential Diagnosis*.)

3. The chief dangers of spinal anesthesia are: Infection, injury to the spinal cord, loss of respiratory power, paralysis, poisoning from the drugs employed, and death.

4. "Concussion of the brain is the name given to the state of unconsciousness immediately following upon a blow on the head. The patient is, in a word, stunned. The symptoms appear immediately on receipt of the injury, and two stages are recognized: (1) The stage of collapse; (2) The stage of reaction. In the collapse

stage there is insensibility of varying severity. The patient can generally be roused, but relapses into insensibility. The pupils are equal, often contracted, and react to light. The pulse is slow and weak; the respirations slow, shallow, and irregular. The muscles are relaxed, but there is no actual paralysis; the reflexes are present; there is incontinence of urine and feces, and a subnormal temperature. When reaction occurs, there is a gradual return to consciousness; vomiting may occur but does not persist. The pulse increases in rate and volume; and the respirations become deeper and more regular. The extremities become warmer, and the body temperature may rise to a degree or so above normal.

Contusions or lacerations give rise to symptoms resembling concussion, but generally of greater severity, the period of unconsciousness being considerably prolonged. The typical symptoms may not appear for three or four days. If the laceration is in the sensorimotor area, clonic spasms may occur affecting certain groups of muscles, or in more severe lacerations, paralysis may result. A group of symptoms apart from sensorimotor symptoms may occur to which the name of *cerebral irritation* has been given. The patient lies curled up on his side, eyes closed, pupils contracted and equal, pulse slow and weak, and temperature subnormal. He can be roused, but resents interference, and will often keep his eyes tightly closed if an examination of them is attempted. The urine and feces are passed into the bed. The condition may last for several weeks, but tends to recovery. In the early stages of laceration a lumbar puncture will demonstrate the presence of blood in the subarachnoid space.—(Pye's *Surgical Handicraft*.)

5. The symptoms of *congenital hypertrophic stenosis of the pylorus* are quite characteristic and show themselves from within a few days to three weeks after birth by vomiting, loss of weight, and constipation. The physical signs are dilatation of the stomach, with visible peristalsis from left to right, and the presence of a sausage-shaped tumor. The progress of the disease is rapid, and from being possibly at first a well-nourished infant, the patient rapidly becomes emaciated. The following operations may relieve the condition: Pylorotomy, gastro-enterostomy, pyloroplasty, and pylorodiosis.—(From Keen's *Surgery*.)

6. In *supracondyloid fracture of the humerus*, "the elbow is flexed at an angle of 120° or 130°, and the forearm, held semipronated, is supported by the other hand. Around the seat of fracture great swelling rapidly ensues. The olecranon projects behind, but the mutual relations of the bony points of the elbow are unaltered. The lower end of the upper fragment may be felt in front above the level of the joint, as a rough and sharp projection, and this sometimes pierces the soft parts and renders the fracture compound. The joint movements are normal, but unnatural mobility may be detected above the level of the joint. Crepitus and localized tenderness may be elicited. The displacement is readily reduced by manipulation, but is usually reproduced when the support is withdrawn. The upper arm is shortened to the extent of about half an inch. In rare cases the obliquity of the fracture is downward and backward, and the lower fragment is displaced forward."

Subluxation of the head of the radius, or "dislocation by elongation," is a comparatively common injury in children between the ages of two and six. It almost invariably results from the child being lifted or dragged by the hand or forearm. The traction and torsion thus put upon the radius causes the front part of its head to pass out of the orbicular ligament, the edge of which slips between the bones. The person holding the child may feel a click at the moment of displacement. The child complains of pain in the region of the elbow; the arm at once becomes useless, and is held flexed, midway between pronation and supination. All movements are painful, but especially movements in the direction of supination. The deformity is slight, but the head of the radius may be unduly prominent in front. From the way in which the injury is produced the wrist also is often swollen, and in some cases the patient is brought to the surgeon on account of the condition of the wrist, and attention is not directed to the elbow.—(Thomson and Miles' *Manual of Surgery*.)

GYNECOLOGY

1. *Atresia of the cervix*.—"Congenital atresia of the cervix may have its seat at the internal or at the external os, or it may affect the whole canal. It is not discovered until after puberty and the institution of menstruation. If there is no associated anomaly of the uterine body or ovaries, the menstrual menses appear regularly and become more painful without the discharge of blood from the genitalia. By a bimanual examination the physician detects a spherical cystic tumor in the pelvis, occupying the position of the uterus. By a specular examination the closure of the external canal and the distension of the cervix may be seen, or if the atresia is higher up it is detected by a sound. Exceptionally there is no attempt at menstruation, and occasionally the menstruation is vicarious. The diagnosis of congenital atresia of the cervix is easily made. It is impossible to pass a sound through the cervical canal. If there has been an accumulation of menstrual fluid or of mucus within the womb, the latter is converted into a cystic tumor with rather thick walls, and on both sides of it there may be enlarged and distended tubes. In atresia at the internal os the external form of the cervix is well preserved. In atresia at the external os the cervix is practically obliterated and becomes continuous with the vaginal vault. By digital examination it is impossible to detect the cervix, but upon inspection through a speculum it is indicated by a slightly projecting nipple in the middle of the vaginal vault, and the seat of the external os is marked by a shallow dimple."—(*Hirst's Diseases of Women*.)

2. *ECTOPIC GESTATION*. *Diagnosis*: "When extra-uterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs*; Nos. 3 and 4 are *probable signs*; Nos. 5 and 6 are *positive signs*."—(*American Text Book of Obstetrics*.)

3. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *acute salpingitis* the pain is not localized, but may be bilateral or just above Poupart's ligament, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender; there may be history of infection and leucorrhea, and the gastro-intestinal symptoms are generally absent.

In *right ureteral calculus*, the pain may be excruciating, and radiates down the course of the ureter and to the genitals; x-ray may show the calculus, and the passage of a ureteral catheter may also demonstrate it; cold sweat and collapse may be present, and the other signs of appendicitis and salpingitis are absent.

4. *Abdominal hysterectomy*.—"The patient must be carefully prepared as for any other abdominal operation, but in addition the pubes and vulva must be shaved and thoroughly purified; the vagina should be douched for some days previously, and an antiseptic dressing worn, and if need be the uterine canal should be curetted and disinfected with some powerful antiseptic.

"After anesthesia has been induced the Trendelenburg position is adopted, and an incision of suitable length made in the median line. The parts are then carefully explored, and if no adhesions exist an abdominal cloth is packed in over the intestines in order to protect and keep them from exposure and injury. If adhesions to omentum or gut are present they must be carefully divided; it is, of course, most desirable that a complete peritoneal covering should be secured for any adherent organs; omental grafts may be sometimes useful in this direction. The broad ligaments are then examined, and a decision made as to whether or not the ovaries and tubes are to be saved.

"A pedicle needle carrying a sufficient length of well-boiled silk is carried through the round ligament so as to secure the ovarian artery and veins, and tied as far away from the uterus as possible. A broad ligament clamp may then be placed in position close to the uterus, so as to prevent venous regurgitation, and the broad ligament is divided half-way down. It is often possible and desirable to pick up the divided end of the ovarian artery on the face of this section and secure it separately, while the little artery which accompanies the round ligament should also be carefully secured. The ovarian artery on the other side is next dealt with in a similar fashion. A transverse cut is now made across the front of the uterus, involving merely the serous membrane and connecting the two ends of the incisions in the broad ligaments; the peritoneum below this transverse cut is detached, together with the bladder, from the cervix, and the intraligamentary space is thereby opened up on either side. In this will be found the uterine vessels, and it may be possible to see and isolate the uterine artery before securing it by ligature. Care must be taken in this part of the operation to keep close to the uterus, as the ureter comes forward from behind under the uterine artery to reach the bladder, lying about the level of the os internum. The uterine vessels are in this way carefully secured and divided.

"The uterus is now merely held by the connection between the vagina and cervix and the peritoneal reflection in Douglas' pouch. If a supravaginal operation will suffice, the surgeon cuts across the neck of the uterus in such a way as to fashion two flaps, and finally the peritoneum behind is divided. A few small vessels will probably need to be secured on the face of the uterine stump. This having been effected, the uterine flaps are stitched carefully together so as to bury the open cervical canal; the uterine stump is then covered in by uniting the divided portions of peritoneum. This line of sutures is carried up on either side so as to secure the two layers of the broad ligament; the final result is that the pelvic floor is covered in by a continuous layer of peritoneum, showing a sutured incision which runs transversely from one side to the other. The usual peritoneal toilette follows, and the abdomen is generally closed entirely, no drainage being required."—(*Rose and Carless' Surgery*.)

MEDICAL JURISPRUDENCE, HYGIENE, AND PREVENTIVE MEDICINE

1. *Civil responsibility* implies that an individual is capable of making a will, signing a contract, marrying, managing his estate, etc.

Criminal responsibility implies that an individual is capable of controlling his actions, that he knows right from wrong, that he realizes that certain acts are forbidden, and that he will be held responsible to the state for the commission of criminal acts.

2. *Insanity* is defined, in Allbutt's System of Medicine, as "such a disorder or disease of the nervous system as prevents the individual from reacting normally as a member of society to which by birth and education he belongs."

Melancholia is a variety of mental disorder, characterized by a general perversion of the mental faculties and accompanied by depression.

Paralytic dementia is a gradually progressive and chronic inflammation and degeneration of the cerebral cortex; it is characterized by failure of memory, changed disposition, delusions of grandeur, and may lead to epilepsy and paralysis.

Paranoia "is a form of insanity which comes espe-

cially under the class of degenerative diseases. It is essentially characterized by a delusion or delusions of a fixed and systematized character. They are usually indeed of one kind, and the disease has perhaps for this reason been called monomania. This is, however, an unfortunate term, as we find this symptom not infrequently in other forms of insanity, as melancholia, where we always observe decidedly fixed ideas of depression. The main fundamental characteristic of this disease is a delusion which has become a part of the belief of the individual, and which he believes himself able to explain and defend."—(Witthaus and Becker's *Medical Jurisprudence*, etc.)

"Idiocy differs from other states of insanity in the fact that it is marked by a congenital deficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it."—(Taylor's *Medical Jurisprudence*.)

3. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order in about twenty-four hours. It is said to be due to the coagulation of the muscle plasma.

Medicolegally, it is a sign of death, and an indication of the length of time that has elapsed since death occurred.

The onset and duration of rigor mortis depend upon the previous degree of exhaustion. In death from exhausting diseases, there is an early onset, while in those dying suddenly, as from accident, it may be delayed for twelve hours or more. Its duration is very variable; it is shortened by heat, and prolonged by cold; it generally lasts about twelve to twenty-four hours; in death by lightning or electrocution it may only last a few hours; in other cases, several days.

4. In general a medical examiner is an agent with limited powers, but, nevertheless, his acts are binding within the scope of his authority, and to this extent the same general rules are applicable to him as to other special agents. The certificate of the medical examiner is conclusive upon the company as to its recitals in the absence of fraud of the applicant in making the representations or in concealing material facts; and in answering the questions of the medical examiner the applicant has the right to rely upon his construction of them at the time and may answer them in the light of such interpretation. So if the examiner, knowing the facts, suggests answers which are made in accordance therewith, the company is bound. Again, an insurance company is bound by the act of its medical examiner in reporting an applicant to be a fit subject for insurance, unless he was purposely misled by the applicant and inveigled into recommending him as a fit subject for insurance when but for such deception he would not have done so. But where the answers of the applicant given to the medical examiner are false and material and are known by him to be so, his conduct in writing them down and in not communicating his knowledge to his principal constitutes a fraud upon the company which is not estopped to set up their falsity. Such examining physician is the insurer's agent even though the application makes him the applicant's agent and his acts within the scope of his authority are binding upon the association and the company is estopped to show incompetency of its medical examiner. The laws regulating the legal relations of the company and its medical examiner vary, however, in the different States.

5. *Natural purifiers of the atmosphere, which keep its composition fairly normal*, are: Winds, rain, the power possessed by the green parts of plants (in sunlight) of absorbing CO₂ and setting free oxygen, gaseous diffusion, movements of the air caused by changes in the temperature, and oxidation processes.

6. *The most frequent diseases of soldiers are*: Typhoid, dysentery, diarrheal diseases, tuberculosis,

pneumonia, influenza, colds, sore throat, measles, mumps, meningitis, scarlet fever, smallpox, and other infections; hookworm disease, yellow fever, cholera, plague, typhus, sunstroke, skin disease, and bites of fleas, lice, ticks.

In selecting a camp site the following conditions should be borne in mind: The presence of water, wood, and grass. The soil should be dry and elevated, with some protection from winds. There should be space enough to accommodate the men without crowding. Old camp sites should be avoided because the soil is certain to be polluted and may be infected. Excess of vegetation and dense woods should be avoided on account of the extreme moisture or dampness which they induce. Marshes and stagnant water should also be avoided on account of mosquitoes.

If tents are to be used these must be such as to afford both thorough protection and good ventilation. They should not be too crowded, either as regards the number of occupants or the location of the tents one to another. If the camp is of extended duration, the tents should be floored, or, at least, the men should not sleep on the ground. A trench should also be dug about each tent to prevent flooding by rains, and from time to time the tents should be moved about, as it is well known that tents occupying the same ground for a length of time become unhealthy. Camp kitchens, stables, sinks, latrines, etc., should be as far from the sleeping tents as reasonable convenience permits, and to the leeward of prevailing winds. All camps should be regularly and carefully policed, and the fact that a camp expects to change its position does not justify neglect of proper policing of the ground occupied.

7. *Sulphur* is a good insecticide, but a poor germicide. *Formaldehyde* is a good germicide, but a feeble insecticide.

8. *Three measures necessary in the prophylaxis of smallpox*: (1) Compulsory vaccination, (2) isolation, and (3) disinfection.

Immunity appears about the eighth day after vaccination.

9. *For success in the suppression of an epidemic*, the health officer must have knowledge of the epidemiology of the disease, particularly of the mode of transference of the infection; if the disease has an intermediate host, or is transferred by an insect, a knowledge of the biology of such insect (or other animal) is necessary.

10. In the registration of vital statistics are included the statistics of births, marriages, deaths, population, diseases, immigration, and emigration.

From a sanitary point of view the most important object of a registration of vital statistics is to ascertain the prevalence of diseases, and causes of death, and to protect the community as far as possible from communicable diseases.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE PRINCIPLES OF MENTAL HYGIENE. By WILLIAM A. WHITE, M.D. 323 pages. Price, \$2.00. Published by The Macmillan Company, New York.

ANNUAL REPORT CITY OF CHICAGO MUNICIPAL TUBERCULOSIS SANITARIUM, 1916. Board of Directors, CHAS. P. CALDWELL, M.D., JOHN DILL ROBERTSON, M.D., F. BOWDEN DEFOREST. 98 pages. Illustrated. Published by the Board of Directors of the City of Chicago Municipal Tuberculosis Sanitarium.

NEUROSYPHILIS, MODERN SYSTEMATIC DIAGNOSIS AND TREATMENT. By E. E. SOUTHARD, M.D., Sc.D., and H. C. SOLOMON, M.D., with an Introduction by JAMES JACKSON PUTNAM, M.D. 496 pages. Illustrated. Price, \$5.00. Published by W. M. Leonard, Boston.

GENERAL PRINCIPLES OF THERAPEUTICS. By FRANCIS H. MCCRUDDEN, S.B., M.D. 183 pages. Price, \$1.50. Published by Gregory, Boston, Mass.

Miscellany.

Kayak Vertigo.—This is an affection occurring among the Greenland Esquimaux, especially in the northern countries and attacks pure and mixed bloods alike. Kayak is the native name of a canoe made of sealskin large enough for only one person who uses a two-ended paddle; it readily capsizes with the unskilled. With his harpoon the Esquimaux hunts the walrus, etc. He has learned to use the boat when a child. Fear of capsizing and drowning is based on the fact that 15 per cent. of the men die from falling into the sea. The vertigo so called is regarded as a modern disease, but occurred off and on before the advent of the whites. As a rule the man is far from the coast when seized and when he is the fit tends to come on, especially when the snow-covered mountains cast long shadows on the water. The "vertigo" comes on very suddenly as an indescribable fear. The subject thinks the canoe is sinking and in trying to "trim ship" may go overboard; or, perhaps, the boat seems heavy and unmanageable or the man himself feels his energy gone. He may have precordial anxiety and palpitation. Vertigo is actually present only in one-third of the cases. If he sees another Kayak his self-confidence returns. Even a neighboring ice floe is better than nothing. The seizure may be followed by great psychic depression, migraine, etc., and one attack is apt to be followed by others and the man must renounce the sea for good. Attempts have been made to use outriggers and two-man canoes, but these reforms take away the special advantages of the one-man boat. Laache believes that the disease is aggravated by the use of coffee and tobacco.

Insanity and the War.—The third annual report of the British Board of Control for the year 1916 states that the number of notified insane persons under care in England and Wales was 134,029, or 3159 fewer than the number for the previous year, although in 1915 there was also a decline of 3278 cases. The year 1915 was the first year since reliable statistics have been available, *i.e.* since 1889, in which there was a decrease in the numbers under care as compared with those of the year preceding. This has now been followed by an almost equal decrease for 1916. During the ten years ended January 1, 1915, the average annual increase was 2251, and had this rate been maintained during the last two years, the total number under care on January 1, 1907, would have been 144,968 instead of the actual number, 134,029. In their previous report the board called attention to the consistent manner in which yearly increases of the number under care had occurred since 1859, and drew the inference that the diminution for 1915, was a temporary one, bearing some relation to the exceptional conditions, social and economic, arising from the war. If this inference was justifiable then it may equally well be drawn with respect to the continued decrease for 1916. On January 1, 1917, there were nearly 2000 mental and nervous cases under observation in military hospitals, of whom a certain number will be probably eventually certified as insane.—*The Medical Officer*, November 17, 1917.

Therapeutic Hints.

Chronic Bronchitis.—In cases of this condition where there is a moderate amount of secretion, the following formula may be used with excellent results:

R Tinct. nucis vomicæ. ṁv to x 0.35–0.70
Tinct. scillæ. ṁxx 1.25
Ammonii carbonatis. gr. iij 0.20
Syrupi tolutani. ṣss 2.00
Infusi senegæ. ad. ṣss
M. et fiant mistura.

Sig.—Three times daily after meals.

From the same source is offered this old formula for use in cases having a great deal of cough but little sputum:

R Tinct. camphoræ compositæ.
Oxymellis scillæ.
Syrupi tolutani. āā ṣj (30.0)
M. et fiant mistura.

Sig.—A teaspoonful from three to six times daily in water.

Often the cough is kept up by an irritable condition of the pharynx, when barley water flavored with lemon will give much relief, especially at night, when it can be sipped as required.

A spray that will aid in producing relief is the following:

R Menthol 1 part
Eucalyptol 2 parts
Benzinol 3 parts
M. et fiant mistura.

Sig.—Inhale from an inhaler or handkerchief.—*Forchheimer's Therapeutics of Internal Diseases*, Vol. III.

Anorexia.—Hare, after giving attention to the proper, nourishing diet needed in the correction of this condition, which is usually a result of some constitutional condition, uses the following formula as an aid in producing good results:

R Arseni trioxidi gr. $\frac{1}{2}$ (0.03)
Extracti nucis vomicæ. gr. iv (0.25)
Quininæ sulphatis gr. xx (1.3)
M. et fiant pilulæ No. xx.

Sig.—One pill after meals.

Or,

R Acidi hydrochloridi diluti. . . ṣss 16.0
Tincturæ cinchonæ compositæ ṣvj 180.0

M. Sig.—Dessertspoonful (8.0) three times a day after meals, well diluted with water.—*Practical Therapeutics*.

Chilblains.—Owen recommends the use of woolen stockings and the avoidance of tight shoes if the feet are affected. When the hands or ears are affected, they too must be protected from weather conditions. The affected parts must *never* be placed in front of a fire after being exposed directly to the cold. The fingers and toes must be bathed daily in cold water, dried with flannel, and a solution of one part iodine to two parts soap liniment applied. He states that the Esquimaux and Indians use oil of turpentine, which may be applied, but should first be mixed with an equal part of olive oil. To relieve itching, apply an ointment of 1 dram of powdered camphor to 4 ounces of vaseline.—*The Treatment of Emergencies*.

THE ACUTE ABDOMEN.*

By JOHN B. DEEVER, M.D.,

PHILADELPHIA.

PROFESSOR OF THE PRACTICE OF SURGERY, UNIVERSITY OF PENNSYLVANIA.

AT the risk of repeating an oft-told tale I have chosen to devote my remarks to the question of the acute abdomen, having in mind more especially acute perforations and gangrene of the appendix, perforating gastric or duodenal ulcer, acute perforating and gangrenous cholecystitis, acute hemorrhagic pancreatitis, and acute intestinal obstruction. The subject is an important one. Indeed, in gravity it is perhaps not exceeded by that of any other acute conditions with which we are confronted.

The picture, more or less familiar to you all, usually begins with sudden local pain, vomiting, and shock, followed by a more or less prolonged period in which the body is attempting to overcome the shock and to repair the lesion and fight the defensive battle against bacterial invasion. Peritonitis, varying with the viscus that has caused it, sets in early along with symptoms of toxic absorption.

The most common type of acute perforation into the abdominal cavity is that of the appendix. As a rule, this produces a diffusing peritonitis, the most severe form of which results from early perforation near the base of the appendix. If the perforation develops suddenly the appendicular contents are poured forth free into the peritoneal cavity, the intensity of the resulting inflammatory process depending upon the amount, the fluidity, the virulence, and the rapidity of evacuation of the contents. The latter having once gained entrance to the general peritoneal cavity, they are rapidly dispersed through extensive portions of the peritoneum by the peristaltic action of the intestines, and a diffuse purulent peritonitis results. When the ulcerative process develops slowly the peritoneum has had time to form a greater or less amount of plastic exudate that completely surrounds the appendix and in the event of perforation a circumscribed peritonitis or abscess develops.

In either case, from these bare outlines of the pathological process involved the seriousness of the condition becomes evident. The primary consideration now is not the treatment of the lesion in the appendix so much as that in the peritoneum. Within the first 24-40 hours of any peritonitis, localizing

or diffuse, the process is confined, that is to say, it is lying free between the coils of the intestines, and with few exceptions at this stage the condition is amenable to surgical interference. The operative mortality in perforating appendicitis is low at this stage, about 1 per cent., but it rises rapidly if first seen after that period and immediately operated upon. This time limit is, of course, not absolute, being subject to modifications according to individual conditions.

The initial symptoms of acute perforating and gangrenous appendicitis do not differ greatly from those inaugurating an attack of uncomplicated acute appendicitis, and it is no doubt difficult to say exactly when an appendicitis goes over into a peritonitis. Some guiding signs are the persistence and exacerbation of the pain and tenderness in the right iliac fossa, followed by extension of tenderness to adjacent areas, increase of pulse rate and of muscular rigidity, the latter being perhaps the most significant, absence of peristalsis, etc., until, in short, the presence of peritonitis is clearly established.

Of all the varying pictures presented by an inflammation of the appendix none is so misleading as that of gangrene of that organ. One reason for this is the insidious nature of the process which allows the toxins to be absorbed without producing marked local indications. Very often at operation in such a case the appendix shows little if any signs of active inflammation, but merely a highly necrotic patch of tissue sometimes limited to the wall of the appendix. Another reason for the deceptive nature of this type of acute appendicitis is sometimes seen in the anatomical conditions present, that is, when the appendix is so placed in relation to the abdominal and pelvic walls as to prevent pressure upon it from without; consequently palpation in such a case will cause comparatively little pain. It is easily seen how this would lead to delayed operation with disastrous results. These quasi-quiescent cases are really in the early stage of a grave if not fatal illness unless the progressing toxemia be stemmed by removal of the offending organ. Every surgeon of experience dreads these cases in which because of their insidious character he is called in to perform "not an operation but a miracle," for it is rarely that the life of a patient in an advanced stage of blood poisoning from gangrene of the appendix can be saved by operation.

Next to perforation of an appendix the most common cause of the acute abdomen is that of a perforating chronic gastric or duodenal ulcer. The pain is of an intense stabbing character referred to the upper abdomen, which soon assumes a board-like rigidity. Very often the downward course of the infection toward the right iliac fossa causes

*Read before the First District Branch of the Medical Society of the State of New York, Newburgh, November 9, 1917.

extreme rigidity at that point and leads to the not uncommon and not unnatural error of accusing the appendix as the *fons et origo* of the trouble. But as a rule, the appendix rarely perforates without some premonitory attacks, and when it does rupture through into the general peritoneal cavity the symptoms are not so alarming nor so prostrating as those of a gastric or duodenal perforating ulcer. Collapse in the latter does not usually appear in the first hour or two, the abdomen at this stage is retracted, not distended, rigid, and exquisitely tender, especially to the right of the median line above the umbilicus. With the escape and the gravitation of the fluid through the opening at the base of the ulcer the pulse rate rises and the abdomen becomes distended. Intestinal obstruction is almost complete. Tenderness becomes more marked and the symptoms of shock are accompanied by collapse. As a rule, after the first onset of pain the patient vomits, but only once. This is an important distinction between perforation and obstruction or strangulation of the bowel. The temperature now generally falls and the pulse rate increases. Thus, in a word, acute overwhelming pain, vomiting, fall of temperature, rise of pulse, shock, and peritoneal reaction, while indicative of a perforation into the peritoneal cavity in general do not designate what part of the gastrointestinal canal is affected. The previous history is, of course, very important, and if this were always clear and always obtainable there would be little difficulty in making the distinction.

The symptom complex of an acute perforation of a chronic ulcer whether situated in the duodenum or in the anterior wall of the pyloric antrum is the same. If presented by a young anemic female the chances are in favor of a gastric location, while if in an adult male the site would be more likely to be found in the duodenum. The latter is much the more frequent site of a perforating ulcer, while in case of hemorrhage the ulcer will more likely be found in a gastric location. Perforated duodenal ulcer also more often gives the typical picture because the ulcer-bearing area is not so easily isolated from the general peritoneal cavity as are the walls of the stomach. Reactive peritonitis involving the parietal peritoneum and the serosa of adjacent viscera usually prevents acute perforation of an ulcer on the posterior wall of the stomach. An interesting exception to this rule came under my observation in a patient who was the subject of three acute perforations—two of the duodenum and one of the posterior wall of the stomach. Operation was performed for each perforation with recovery. It is, however, not generally possible to make a positive pre-operative determination of the position of a perforating peptic ulcer, nor is it important. The most essential point is to prevent the catastrophe by proper treatment—surgical, as a rule—of the underlying causes that lead to it. It is rarely that in any of the acute abdominal conditions under consideration that a warning signal, in the form of some more or less pronounced digestive trouble, has not been displayed at some time or another of future trouble.

What ignoring such a signal means is perhaps best illustrated in acute perforating or gangrenous cholecystitis. Only recently William Mayo has

called attention to the fact that in his experience, perforation of a gall-bladder has been one of the most fatal of the different types of acute perforation. He attributes this to the fact that the cases come to operation late because the patients, usually having had one or more attacks of gallstone colic, consider the condition to be merely a repetition of such an attack, and surgery is not resorted to until the ominous sign of "too late" dooms the patient.

The significance of the foregoing becomes all the more apparent upon consideration of some of the factors that create a predisposition to the development of acute cholecystitis. Prominent among these are previous attack or attacks of inflammation of the gall-bladder, the exciting microorganism of which may remain latent for a period and superinduce a recurrence at some future time. Furthermore, a gall-bladder once infected will almost always be subject to repeated attacks, and the sequelæ of such repeated inflammations are often more serious than the original disease—gallstone formation and the impairment of health due to the development of pericholecystitic adhesions. The action of gallstones makes an easy path for infection to reach the gall-bladder; indeed, anything that causes biliary obstruction increases the chances for infection of the gall-bladder, and in the ordinary course of events infection is the primary factor in the etiology of acute cholecystitis.

The clinical picture of this disorder may range in severity from a mild, uncomplicated, catarrhal inflammation to a suppurative and eventually a phlegmonous, a perforating, and a gangrenous cholecystitis. The symptoms vary little, the results of infection differing with the increased virulence of the bacteria rather than with the kind of responsible microorganisms. Their virulence also influences the severity of the symptoms. The pain may be dull, aching, severe, and continuous, with acute exacerbations, or paroxysmal, as in typical gallstone colic. The initial pain usually appears in the epigastrium, but soon localizes in the right hypochondrium. It is sometimes referred to the right shoulder blade and very frequently to the right iliac fossa, suggesting appendicitis, with which, in fact, it is very often associated. Nausea and vomiting are always present, and, in the more severe cases, tenderness and muscular rigidity are marked, as in all acute abdominal conditions. Jaundice is absent so long as the common duct and the hepatic duct remain patulous.

It is true that in a certain percentage of mild acute cholecystitis the symptoms subside in about ten days or less, but it is the effect on the general health that gives the picture its serious aspect. I repeat, an infected gall-bladder seldom, if ever, regains its normal condition, and subsequent acute or chronic inflammation and the formation of gallstones are the phenomena to be expected. These are the remote effects which in their turn again give us the original picture with perhaps the addition of more serious features; and the time will come when an acute attack will fail to subside and we are confronted with a suppurative inflammation of the gall-bladder or the more grave conditions of phlegmonous, perforating, or gangrenous cholecystitis. In most instances the severer forms of infection occur in connection with cholelithiasis. The symptoms are

those of uncomplicated acute cholecystitis greatly aggravated, with much more pronounced indications of peritonitis, in fact, of infection of the general peritoneal cavity rather than of the gall-bladder alone.

The chief danger of a suppurative cholecystitis is perforation with the possibility of a local peritoneal abscess or, as we have seen, of a fatal peritonitis. The appendix is often involved and may also perforate; it is often difficult to say which is cause and which effect.

Another lurking menace of repeated inflammation of the gall-bladder is the effect on the pancreas with which it is in such close anatomical and physiological relationship. Infection of the pancreas has been satisfactorily demonstrated commonly to occur by way of the lymphatics which form a rich anastomosing network in the retroperitoneal tissues about the pancreas. Not only this, but there is sufficient evidence to show that pancreatitis may arise in the same way from ulcer, especially in the second portion of the duodenum, and also from colitis, as well as from more distant foci, the appendix and the pelvic organs.

The overwhelming, sudden seizures of the acute abdominal conditions thus far discussed are repeated and exaggerated in the symptoms of acute pancreatitis. The mortality of the disease is high if unoperated, and high enough, in the author's experience (21 per cent.), in operated cases. The pain is agonizing and prostrating and more or less constant, with a tendency to localize in the epigastrium or to radiate to the left. Vomiting is persistent, and this together with the very obstinate constipation is apt to lead to a diagnosis of intestinal obstruction. Tenderness and muscular rigidity are marked, but not extremely so. The pulse is rapid and small and the temperature may be normal, subnormal, or elevated.

Acute pancreatitis usually falls into three types—ultra-acute, acute, and subacute. The ultra-acute cases, with their sudden onset of symptoms of profound shock and profuse hemorrhage into the pancreas and its surroundings, are rapidly fatal, and although the primary shock may abate somewhat death usually ensues within three days. The pancreas will be found infiltrated, hugely swollen, and more or less gangrenous and necrotic.

The prognosis of the acute type is only little brighter than the first. The onset is just as sudden, though less severe, and the hemorrhage is apparently not so profuse and does not involve the entire organ. If the patient survive the early toxemia, improvement gradually sets in, operation will show that a part of the pancreas has either been unaffected or has recovered itself. The affected portion undergoes necrosis and gangrene and, as a rule, suppuration ensues promptly. In exceptional instances pyogenic abscess develops, and recovery takes place with the formation of an aseptic hemorrhagic cyst. The usual result, however, is sepsis and, unless relieved, death.

Subacute pancreatitis is the more common type of the disease and is more amenable to treatment. It is usually limited to the head of the organ, hemorrhage is not so constant a feature, and when present is small. As a rule, there is no hemorrhage but the head of the pancreas is swollen and tender, though it is

not often distinctly palpable. The symptoms of pain, nausea, and vomiting are less severe than in the preceding forms and more often than not a diagnosis of acute indigestion is made. The pulse and temperature are not always affected, unless complicating inflammation of the organ is present. Acute cholecystitis often either inaugurates or accompanies the condition.

Fortunately, acute pancreatic disease is among the less frequent causes of acute abdominal crises, for it may be said to head the list as far as exquisite suffering and unfavorable prognosis are concerned.

From this almost hopeless condition let us turn to a more frequent one and one which with *early recognition and prompt operation* presents a more favorable outlook. About one fourth of the causes of acute abdomen, exclusive of intussusception, are said to be due to intestinal obstruction. Its onset does not differ greatly from symptoms of perforation of a hollow viscus except that vomiting is more persistent and continuous. The pain is distinguishable from the pain of peritonitis by being so much more susceptible to palpation than to percussion; and the rigidity, so typical of peritonitis, is usually absent, the abdomen being relaxed during the intervals of pain. Peristalsis can frequently be excited by abdominal friction, and the lower bowel may be emptied, but there is total obstruction of the upper bowel neither feces nor flatus being passed. The patient also is restless and tosses about to find a comfortable position.

The pain usually begins in the umbilical region, and varies in constancy and degree according to the seat—high or low—of the obstruction; a high obstruction usually produces the more severe type of pain. The temperature shows little, if any, rise and the pulse is little changed at first, acceleration and reduced tension appearing later on. A variety of causes may be responsible for the crisis. Among the more common ones are: a fibrous band which may be constricting the bowel, or beneath which a loop of intestine may be strangulated; or the bowel may be kinked by adhesions; or obstruction may be due to strangulation of an internal hernia, as when one loop of bowel slips into another or into one of the many peritoneal pouches; or the sudden impaction of a gallstone in the small intestine; sudden stricture of the small intestine or colon; or a sudden twist of the bowel.

The cause of the obstruction, however, is not a matter of importance. The thing is to recognize the condition and to bring it to operation at the earliest possible moment before septic absorption and inflammation lead to grave and hopeless peritonitis.

Not long ago I had occasion to observe an interesting case of the internal hernia type of obstruction in which a knuckle of gut had become engaged in a congenital hole in the mesentery. The patient, a young man, while cranking his automobile was seized with a sudden and agonizing abdominal pain. He was brought to the hospital moribund, and at autopsy the condition as described was found.

In this brief summary of the causes of the acute abdomen it is not difficult to discover in each, with the possible exception of the last-named, a logical chain of events whose beginning can usually be read in the case histories coming under the head of the various gastralgias and whose final outcome will be

found under one or the other of the desperate conditions described. This does not necessarily imply that no digestive disorders are amenable to treatment other than surgical, it is intended merely to emphasize the fact that it is only exceptionally that the histories of these acute conditions fail to reveal some gastric disturbance, sufficiently marked at some time or other to have warranted the suspicion of more trouble to come. Since such warnings continue to be ignored or unrecognized, it is well to know what to do to avoid a fatal outcome in the event of perforation of an abdominal viscus with the development of peritonitis.

The greatest factor in the mortality of peritonitis is undoubtedly delay in surgical intervention for the lesion which gives rise to it. And next in importance is faulty method of treatment at the onset of acute conditions preceding the peritonitis. The main point in caring for the latter is complete physiologic and anatomic rest for the purpose of preventing the spread of the peritoneal inflammation, for it is the spread of infection that does the fatal work. The abdomen protects itself from this spreading infection chiefly by surrounding itself with a plastic exudate which walls it off from the general cavity, and this can be accomplished only by rest. It has been demonstrated that it is the phagocytic action of *Staphylococcus albus*, present in this exudate that creates a local immunity against infection (after the initial leucopenia is over) and maintains leucocytosis. The leucocytes do not degenerate in its presence as they do in the presence of the bacillus colon, for example. It also causes sufficient reaction (harmless to the host) to produce agglutination and adhesions which tend to limit infection. It appears early, in fact, it is the first microorganism to appear and the last to disappear in intestinal infection. The natural peristaltic movements prevent the formation of this protective covering and they must therefore be inhibited. No food should be given by mouth and above all nothing in the nature of a laxative or a purgative. To illustrate the importance of this let me give you figures from some of my cases of acute appendicitis, apropos of the question of purgation.

In a series of 259 operations for acute appendicitis 79 (30.5 per cent.) had been purged before admission. At operation, in all but two of the 79 the appendix was either perforated, gangrenous, acutely ulcerated, or surrounded by an abscess. The two exceptions showed merely a simple catarrhal inflammation. It is about as logical to purge these cases as it would be to rub an inflamed eye or to prescribe active swallowing movements for tonsillitis.

In view of the discovery that the lower abdominal viscera possess relatively little power of absorbing the toxemia from bacteria, and exudates compared with the active and rapid absorption of the same inherent in the diaphragmatic areas, it is important to direct the possible spread of infection downward toward the pelvic region. This is best accomplished by the Fowler sitting position.

Another preoperative measure which is of immense value is the Murphy method of enteroclysis. Having deprived the body of fluids by mouth, we have in this an invaluable means of providing a continuous supply of the necessary fluid through the large bowel, with a minimum of motion. Not only

this, but circulation is stimulated by it, the kidney and other functions are resumed, and the toxins eliminated, and the patient is given a fair chance of resisting the infection.

Ice bags are of value but only in relieving pain and lessening peristalsis, but they do not and cannot reduce the inflammation.

Operation in these acute abdominal crises presents two important aspects—time and technique.

In appendiceal peritonitis of less than 40 hours' duration immediate operation has given the best results. But in cases of longer duration there are several factors to be considered. Where there is a tendency for peritonitis to localize, or to form an abscess, and the temperature, pulse and leucocytosis indicate that the body is successfully combating the toxins—immediate operation is indicated unless the localization and subsidence of general symptoms have been rapid, marked, and unmistakable. In such an event delay would prepare the way for still more favorable conditions for operation, which can then be done at once as soon as improvement appears to have reached a standstill. It seems superfluous to add that even with favorable localizing signs indication for operation will depend on the patient's general condition. Where this is good and there is evidence of a localizing process it is not necessary to wait until there is a distinct sharply outlined abscess. The time to operate is when temperature and pulse have attained an equable level and consistently high leucocytosis shows good resistance to the toxemia, and the free passage of flatus indicates the re-establishment of peristalsis. If in addition there are signs of a deep-seated mass of resistance in the right iliac fossa, operation will, as a rule, disclose a limited peritoneal inflammation.

But in progressing peritonitis, if due to appendiceal perforation of more than 40 hours' duration, delay is the best policy. The time to operate in these cases will depend very much on the patient's condition. It is safe to presage a fatal outcome if operation be undertaken in the presence of symptoms of diffusing peritonitis—rapid running pulse, abdominal distention, cyanosis, and the facies Hippocratica—while delay may save the patient in such cases, as has already been indicated.

As to the technique of operation. Removal of the appendix is, of course, imperative except when a circumscribed abscess would present the risk of spreading septic material.

Lavage of the peritoneum is unnecessary and harmful. The pus should be removed in the gentlest manner possible, especial care being taken not to disturb the protecting coat and lymph frequently found on the intestinal serosa. It is not this lymph which causes subsequent adhesions. The latter are more likely the result of trauma or rough handling of the bowel during operation. Tubes are best for drainage, and a glass tube through the incision or a stab wound in the pelvis is most essential; for obvious reasons it is this region, even more than the operative field, that should be provided with free drainage. After operation the patient is again placed in the Fowler sitting position and the preoperative treatment resumed until gradual improvement justifies a normal convalescent régime.

In the treatment of perforating peptic ulcers the most important single factor is the time at which

the operation can be done. From my experience, and with modern technique, I have no hesitancy in saying that every case of perforated duodenal ulcer operated on within the first twenty-four to thirty hours should get well. I have now operated on fifty-one such cases of acute perforation with but one death, and that was in a case operated on over seventy-two hours after perforation had taken place. I have not refused to operate in any case that was not frankly moribund.

It is my practice to perform a primary gastrojejunostomy after closing the perforation. It adds but little to the time, and these patients are not usually severely shocked. It enables the surgeon to make a secure closure of the perforation or even to plicate the duodenum without fear of encroaching upon its lumen, and the suture line is not exposed to strain and danger of leakage. Convalescence is smooth and the cure permanent. Gastroenterostomy is curative in many cases, and, as a rule, the nearer the ulcer to the pylorus the more likely is the anastomosis to be effective. To my mind it is the only proper procedure for the expert surgeon to pursue both when an excision cannot be done or as a supplement to excision of a bleeding or perforating ulcer. The occasional operator, unaccustomed to doing a gastrojejunostomy, had better content himself with simple closure of the leak. My immediate results as well as the end-results I have been able to obtain justify me in advocating the combined operation. Whenever the condition of the patient permits I also remove the appendix and examine the gall-bladder and remove it if found diseased.

In the treatment of acute gall-bladder conditions also the most vital item is operation before the toxins of the perforating or gangrenous gall-bladder have had time to get in their pernicious and usually fatal effects. There here arises the much discussed question of cholecystostomy versus cholecystectomy.

In the hands of the expert the two operations are about equally safe, so that much will depend on concomitant circumstances in deciding which procedure to adopt. I prefer the radical operation wherever possible, and therefore do a cholecystostomy only when the condition of the patient, the pancreas, etc., makes the step obligatory.

The arguments in favor of cholecystectomy are to my mind convincing. First of all, we now know that all things considered it does not materially affect the comfort of the patient. From the Mayo Clinic* we learn from experimental as well as postmortem observation on ectomized subjects that the most vital change after removal of the gall-bladder is dilatation of the common duct, which in a sense may be considered compensatory. Removal of the gall-bladder not only greatly lessens the chance of recurrence of gallstones, if such have been present, but it is known also to cure pancreatitis, and also pancreatic lymphangitis, the forerunner of disease of the pancreas. In most cases of the latter the primary source of infection is in the gall-bladder whence it extends along the lymphatics into the glands and through the lobules of the pancreas. And if, as is claimed by some investigators, pancreatitis results from irritation due to bile entering the pancreatic ducts,

rather than to bacterial influences, the dilatation of the common duct that results from cholecystectomy also affects anatomical conditions, so that the bile is led to flow directly into the duodenum with little, if any, back pressure and the pancreatic tissues are thus protected from its irritating action.

Thus, without entering more deeply into physiological details, it is quite evident that in dealing with the diseased gall-bladder in the conditions under consideration the radical operation should be chosen whenever warranted by existing conditions.

In acute pancreatitis the stage at which operation should be undertaken differs with the type of the disease. In a fulminating ultra-acute case, the rapid progress of the patient from bad to worse may make early operation imperative in order to give him a fighting chance, for that is all it would be. But in general it is of advantage to wait a short time to give the body a chance to prepare itself, so to speak, for a still greater tax upon it; but this is a matter of judgment acquired only by experience.

In operating on the pancreas we may choose one of two routes: through the general peritoneal cavity, or extraperitoneal through a loin incision. The latter allows approach to the pancreas, especially its tail, without entering the general peritoneal cavity, which is of great advantage, but it allows no free exposure of the parts and radical surgery is impossible, while concomitant lesions, gallstones, etc., cannot be reached by this route. It is only feasible where the symptoms point to the localization of inflammatory exudate or pus in the loin.

The transperitoneal route is in order in a beginning pancreatitis when the localizing symptoms are all epigastric, when there is a palpable tumor, and when the diagnosis is in doubt. Once in the general peritoneal cavity, the pancreas itself can be reached either through the gastrocolic omentum or through the lesser omentum or through the transverse mesocolon. While presenting the serious disadvantage of the risk of infecting the general peritoneal cavity, the advantages are: free exposure of the operative field, opportunity for radical surgery and for establishing adequate drainage; a most important item whether the disease be in a presuppurative or in a hemorrhagic state. In a case of acute hemorrhagic pancreatitis, having approached the organ through the intraperitoneal route, the only possible procedure is to apply the tampons and drains freely to the organ itself going either above or below the stomach, according to circumstances. Tube and gauze drainage is essential. The pancreas should be freely incised in a longitudinal direction or numerous blunt punctures should be made in its substance, thus giving free exit for the contained blood, lymph, and obstructed secretion. Both gauze and tube drainage should be conducted to the surface through an enveloping sheet of rubber dam to lessen the chance of adhesions to the stomach and intestines.

Any free fluid in the peritoneal cavity should, of course, be removed by gentle wiping, since this pancreatic exudate of itself contains sufficient toxic material to cause death. Drainage of the pelvic cavity with the patient in the semi-erect position is in place here, as are the postoperative measures alluded to in discussing the other acute conditions under consideration. A typical antidiabetic diet has been found useful in so altering the pancreatic se-

*Judd: Collected Papers, Mayo Clinic, 1916, Vol. VIII, p. 282.

cretion as to make it less active and less irritating, and likewise in promoting healing of recent as well as of old pancreatic fistulæ.

In spite of the improvement in the mortality of minimal lesions acute intestinal obstruction has shown little if any improvement in this respect for the past few decades. The reason for this is delay in recognizing the symptoms, and resultant delay in operation. Diagnosis is usually not made until the patient is moribund, and then we are confronted with that favorite reproach "the operation was successful but the patient died." So I would say, do not wait, do not give opium, for it masks the symptoms, but send for a reliable surgeon and let him do the rest. The outcome will usually be satisfactory to all concerned.

STUDIES OF SOME BORDERLINE CASES AMONG CRIMINALS.*

BY LEON EMILE DUVAL, M.D.,

WASHINGTON, D. C.

JUNIOR ASSISTANT PHYSICIAN, ST. ELIZABETH'S HOSPITAL.

AMONG the populations of prisons and of hospitals for the criminal insane we frequently come in contact with cases which are difficult to classify from the standpoint of the mental status. They show no symptoms which place them in the list of those who are definitely mentally ill, yet they cannot properly be classed as mentally normal. It is the object of this article to study some examples of these cases, to work out, if possible, some of the etiological factors which lie at the bottom of their conflicts with society and its laws, and to show the difficulty we have in knowing what to do with them. Often it devolves upon the psychiatrist to determine the degree of responsibility in a given case, and upon his verdict depends the individual's destination, whether to prison or insane hospital.

More and more we of today are coming to realize that crime, vice, drink, and poverty are due to mental unfitness on the part of the individual to cope with the world, in these days of selfish struggling against our fellowmen for the material things of earth. As the years go by, society is requiring more and more of the individual—is making it increasingly difficult for him to keep his place in the struggle for existence. More and more complex are the conditions to which he must react, and his adaptability must increase accordingly, else he falls behind, fails "to keep up his end," and goes to a lower scale in the social standard. Is it any wonder, then, that those who come into the world without a strong physical and mental endowment are apt to find themselves unable to measure up to these standards, and become parasites instead of useful members?

We are beginning to realize that the criminal should be regarded in the same light as the mentally diseased patient, and should be studied with as great care. We are learning that mere punishment of the offender will not safeguard us from further offenses on his part when he regains his liberty. True, there are those who are mentally sound and morally responsible who deliberately offend the law, but

they are in an ever-increasing minority when carefully studied by those who understand the abnormalities of the mind. As yet only too few of the offenders are studied and placed in one of the two classes—of those who are responsible for their misdeeds and those who are not. The psychiatric clinic at Sing Sing is an excellent example of the work which should be carried out in all prisons and institutions where criminals and delinquents of various kinds are confined. The function of classifying these individuals is not an easy one, and even when the cases are carefully studied, it is not always possible to say with any great amount of definiteness what the individual's degree of responsibility and fitness for extra-institutional existence may be.

In the present article I am not considering the high-grade mental defective or moron, because much has been written concerning the high percentages of these individuals in the criminal population. These people get along very well while in institutions, are often excellent workers, more or less efficient at manual labor, quiet and peaceful so long as they are under institutional care, but unable to exist for any length of time outside before being committed to prison or insane hospital. In prison, or when put under mental strain, they often show manic-depressive or precox-like episodes. Manifestly the reasonable treatment of these cases is confinement in colonies, under proper supervision, where they may ply their trades and be more or less self-supporting.

Another class, now coming to be recognized, and belonging to the type of cases which forms the subject of the present article, are the constitutional inferiors and the psychopathic personalities. Gifted with normal intellect, as gauged by Binet-Simon, Yerkes-Bridges point scale, or similar tests, the history of these individuals is that of continual maladjustment to their environments. They do not lack in the ability to work—they are able to learn skilled trades or to achieve such educations as their facilities afford; yet they lack stick-to-it-iveness, steadiness of purpose, coolness of judgment, in fact the mental stability which enables the average man to find his place in the world, and keep it or better it. They are very apt to come into conflict with the law, for among this class are often found individuals with absence or blunting of the ethical sense. Tramps, petty fakirs, and beggars are apt to belong to this class. A history of having led a tramp life and of having served prison terms for various offenses is the rule among this class of patients. The so-called psychopathic personality is often seen in individuals who possess a high degree of intellect, often accomplished, and giving, to the casual observer, every evidence of poise and efficiency. Yet these cases always give the same sort of history—inability to cling to one line of work or to adapt themselves properly to the personal problems which they must meet at times. Questioned about the unsavory incidents of their lives, they shirk the responsibility for their misdeeds by calling themselves the victims of circumstances, or by speaking of their prison sentences and conflicts with the law as if they were the usual, every-day incidents of a man's life. Sometimes they realize their own inability to adapt properly, but as a usual thing they lack all insight into the reasons why they cannot live in harmony with society and its conventions.

*Read before the Clinical Society of St. Elizabeth's Hospital, Washington, D. C., Oct. 29, 1917.

At the basis of most of these cases we find poor heredity. In very few cases indeed have I been unable to find at least one or two of the ancestry showing mental or nervous stigmata. Heredity in itself, however, is merely predisposing to mental imbalance. The precipitating cause is found in the mental conflicts which the individual must meet sooner or later. All of us have our problems, but the tainted individual is poorly equipped with the adaptability necessary to meet his life problems successfully.

The length of time he is able to live in the world before coming in conflict with society's conventions depends upon the amount of mental stability he possesses and his relative freedom from mental strain in the form of mental conflicts. Often the reactions of these individuals are quite childish. Among those I have observed, the sulking and pouting when they are displeased resembles nothing so much as the spoiled child's method of showing disappointment. It is rather striking when it occurs in men of intellectual and physical vigor—men who have tramped Alaskan trails, led the hardy life of the soldier or miner, or accomplished some little success in business or profession. But we note that although they were efficient in their respective occupations, they did not "stick," were never really contented with their lots, and seldom met successfully any of their life problems.

In the lives of all of us come times when we must meet unpleasant situations, in circumstances where there seems to be no comfortable or acceptable solution of our difficulties. In those of normal mental stability such situations are met as best they may be, and in due time the failures and disappointments are submerged and sublimated in the onward and upward rush toward the fulfillment of our ambitions. To the normal individual the failures and difficulties are mere sign-posts on the road of life, and he utilizes the experiences gained by them to avoid similar situations hereafter. This is precisely what the psychopathic individual cannot do. His ability to stick to one line of endeavor is a variable quantity, but he is fairly consistent in his inability to meet his life problems squarely, and either solve them or sublimate them. Give him a situation he cannot meet satisfactorily, and he comes to a full stop, for the mental conflict accompanying the situation begins to control his life and progress. The twin demons of indecision and discontent stand in his way, and only those who are afflicted with the curse of an indecisive mind can really understand what a tremendous obstacle it is to any progress one tries to make.

Just what such an individual's reaction will be to a given situation will depend upon the seriousness of the situation and the relative mental stability the individual possesses. If the situation is sufficiently serious it throws the balance over into a definite mental upset, or leads him to do things he would ordinarily avoid. The individual with a paranoid makeup, who has some grievances which he cannot get settled to his satisfaction, may finally take justice into his own hands, because the situation becomes unbearable and he sees no other way out of it.

When such individuals come to grief and enter an institution, those who study them can often work

out the reasons which led to their conflicts with society, in the form of personal conflicts which had come to the unbearable stage. Unable to solve his problems, each takes the path of least resistance, and when society demands that he pay the penalty for his misdeeds, by robbing him of his liberty, the added strain of prison life proves the last straw necessary to throw the balance on the side of real mental illness, and various forms of prison psychoses are apt to result. A "prison psychosis" may be simply a situation psychosis, clearing up when the man is given his freedom; it may be the bringing forth of a latent mental disease which had been kept under the surface, held back until prison discipline proved more than the individual could react to; it may be manic-depressive or precoc-like episodes which are of brief duration; or any form of mental disease which the individual has a tendency to develop and which would have developed under any equally unpleasant situation.*

Many of these prison psychoses are brief in duration, and when the individual is transferred to an insane hospital he is either convalescent or entirely cleared up. In such cases it is at times very difficult to find anything pathological in examining the patient, and we must depend upon a careful study of the individual's past life and an investigation of his adaptations to his surroundings and of his reactions to the various problems which have confronted him.

Prison life is well calculated to bring out latent traits; I have frequently been told by a patient that he had committed sexual perversions in prison, though his previous sexual life had been normal. The environment of the prison, like that of any body of men shut off from the society of women, as in army or navy life, favors the lifting of mental barriers against such acts. Even when not actually performed their mention is common in the conversation of prisoners, soldiers, and sailors, and in latent homosexuals, these things act as exciting factors in causing mental conflicts. They do not, as a rule, realize the nature of their conflicts—their reactions being apt to assume the form of paranoid ideas referring to their comrades—ideas that they are called vile names, accused of perverted practices, and the like. One latent homosexual, who has no insight into his condition, declares "I can't bear to have a man touch me. I feel as though a snake were crawling on me every time a man puts his hand on me, accidentally or otherwise." This, of course, is a defense reaction.

Prison life also brings out other innate traits, such as a tendency to meditation, introspection, or seclusiveness. In those so inclined it is easy for these traits to merge into depressions or catatonic states, perhaps mild in degree, perhaps marked. Hysterical episodes are frequent among psychopaths, and not infrequently they have no recollection of them at all when they reach the insane hospital. An extremely effeminate individual underwent such an episode in prison, during which he made open and unashamed homosexual advances to every one who came near. On reaching this institution he was in his normal mental state, but had absolutely no recol-

*There may be some dissension in regard to my idea of what constitutes a "prison psychosis." I intend to make this the subject of an article at some later date.

lection of the episode. This forgetting is explainable on the basis that it is the thing of which we are ashamed and which conflicts with the customs of society which is soonest relegated to the realm of the unconscious. These hysterical and other types of episodes are defense reactions against prison environment or other uncomfortable situation, though we cannot always work out a satisfactory mechanism in a particular case.

Two characteristics which I have observed constantly among these borderline cases are—first, a tendency to assume the rôle of martyr in all unpleasant circumstances; second, a tendency to assume a self-sufficient air, which is plainly a compensatory reaction. If one of these individuals has some difficulty with another patient, and he is asked to explain the reasons for certain of his misdeeds, or questioned as to his lack of success in life, he is almost certain to lay it all to circumstances beyond his control, or to the malice of others. I do not mean to say that all of these patients are of paranoid makeup, but they never blame themselves for their lack of adaptability or their numerous misdeeds; they always have some explanation as to why they could not do otherwise than they did. Related to this trait is the tendency to be excessively self-sufficient. As the mental defective often shows a pseudo-solemnity, and an air of grave meditation, so the psychopath assumes a superior, often overbearing air. The psyche recognizes the inferiority, and the reaction is the exaggerated self-sufficiency. In a few cases I have seen the two traits mentioned above were the only departure from normal that I could discover.

Restlessness is another characteristic of many of these individuals. They cannot remain long in one position, because they dislike anything which smacks of routine. They are unable to resist a wanderlust, which is a common trait among them. In the ward they are constantly asking for this or that favor, never satisfied unless something is being done for them. They are impatient over delay of any sort, and cannot understand why their cases cannot be taken up immediately by the authorities. Often they are antagonistic toward other patients, and even when they realize that those who annoy them are insane, are apt to overlook the fact, and conflicts are not infrequently the result. Selfishness is another trait commonly seen, though I would not apply it to the class as a whole.

These "borderline" cases, then, consist of the constitutional inferior, the constitutional psychopath, and, one may add, the high-grade mental defective, who is able, by means of the "polish" he picks up here and there, to give to the casual observer the appearance of being of normal intelligence. They present widely varying grades of mental instability and lack of adaptability, and each case is a law unto itself, in so far as the individual's degree of responsibility and chances for success in life are concerned. No two individuals have exactly the same life problems to meet, and it is possible to acquire a certain amount of mental stability in some cases. In passing on a given case we must rely largely upon what the individual has been able to accomplish in the past, and the evidence his record gives as to how he has met his problems. He may be of a makeup that fails lamentably

whenever he faces a problem, or he may be stable enough so that only once or twice in his lifetime will he meet a situation sufficiently severe to overthrow his mental balance.

Prognosis as to future chances of mental upsets, or as to likelihood of winning success in life must be very guarded. One cannot foretell what the individual's problems are to be, or how he will meet them. These individuals always make sweeping promises as to their future conduct, and make high resolves, but, like the chronic alcoholic's pledge of future temperance, they are of little avail.

There are all possible gradations of these borderline cases, from those in whom only an expert can detect anything abnormal, to those just on the safe side of the opposite near-pathological border. It is not uncommon to meet cases in which the individual acted rashly in some uncomfortable situation because of inability to solve it properly, and in which his committal to the psychopathic ward is based upon this one rash act; when the patient is examined he is found to be quite stable in ordinary everyday life and fully cognizant of the poor judgment he displayed in acting as he did. Such an instance was the case of W. B., given below. This man has always been very efficient and intelligent, and had a good army record; he shows, at present, nothing pathological, but is an inherent homosexual and his desertion, explained by him as due to his wife's desperate need of him, was really part of an effort to convince his unconscious mind that he loved his wife, when, as a matter of fact, he has found the marriage tie unsatisfactory and will not admit it to himself. He is able to go into the world and earn a good living, and his associates will see little, if anything, which is not normal. He is one of the cases which are just under the normal border, and only to the initiated is there anything in his makeup which is not compatible with his leading the same life that any normal person leads.

The question of the disposition of this class of cases is a very puzzling one. We have no right to hold a man who is not insane, and from a legal standpoint most of these borderline cases are sane. But we know that while they are capable of self-support and can exist comfortably so long as they are not under stress, yet they must meet such stress sooner or later, and their return to prison or insane hospital is a matter of time.

From the legal standpoint, too, we are often at a loss to say whether the patient is responsible for his crimes or not. The psychiatrist may be asked "was or was not this man mentally sound at the time the crime was committed, and what was his degree of responsibility?" Of course we have to take into consideration the facts in the particular case; but what are we to say in the case of an individual not insane, but plainly a mental inferior or psychopath, who is not responsible for his poor heredity, but is able to distinguish right from wrong and appreciate the seriousness of his misdeeds?

The answer, as I see it, is a careful study of such individuals, classifying them as to intellect, mental stability, and moral responsibility, and colonizing them in such a fashion that they may lead normal lives, be useful members of society, and yet be under supervision of persons trained for the work.

The chief object of this plan would be to remove them from all such situations and responsibilities as they could not meet properly. It is difficult for the lay mind to understand why a person whose intellect is normal, who has no delusions, hallucinations, or other manifestations of insanity, should not be allowed freedom and the responsibilities of citizenship, or why he should be regarded as mentally abnormal. Nevertheless, these individuals who are near the borderline are not able to exist comfortably unless under supervision, and can lead useful lives only when they have someone to direct them in meeting their problems. There should be no stigma attached to such individuals, if colonized as suggested, and the public should be made to understand the purpose of this grouping of such cases.

One great objection to this plan is the large number of such cases which can be found in any population, far too large to make the plan practicable, it seems to me. Again, I believe that there would be considerable difficulty in making enforced residence in such colonies legal, for the individual would argue that since he was neither insane nor guilty of a crime, there was no legitimate ground for depriving him of his liberty. So we are no nearer a satisfactory solution of the plan than before.

However, the chief object of this article is the study of some cases I have encountered recently, and I will pass on to them. They are selected from records I have made in the routine examination of new admissions in the department of the institution which is devoted to the care of the criminal insane, and comprises Federal, military, and civil prisoners. All were admitted within the last year. My object in presenting them is to study some typical borderline cases as seen among criminals, and to trace, if possible, the relation of the mental state to the crime committed.

CASE I.—Constitutional Inferiority.—A. B., a Highlander by birth, of Jewish extraction, aged twenty years, was arrested for desertion from the Army. While awaiting trial he began to manifest hysterical laughter and epileptiform attacks. Sentenced to a year at Fort Leavenworth prison, these attacks continued, but the prison physicians suspected malingering. An apparent suicidal attempt, and strange behavior on the part of the prisoner caused him to be transferred to this institution, where my study of him elicited the following history:

Born as one of the younger children of a nervous mother, the patient's home life was far from pleasant. He worshipped his father, who was always busy and, instead of returning the boy's affection, was rather indifferent to him. At the age of twelve the father began to accuse the boy of masturbation, and to punish him for real and fancied offences in this direction. He constantly threatened the boy with the layman's idea that the practice causes insanity, and that it would be the means of putting him in an insane asylum sooner or later. School life was a bore to the sport-loving outdoor heart of the boy, and he made poor progress in his studies, in spite of the fact that he was quite intelligent and was given every educational opportunity possible. The boy used to run away from home and stay weeks at a time; on his return he was always punished severely and sent to some training school for boys. He reached the first year of high school and then, because he made such poor progress and lacked interest, his father obtained work for him in a store. He soon tired of indoor work and of the continued beratings of the father, who, as has been proven by letters written to the boy while here, has never had a father's love for this particular son, though proud of the other children, who have been more successful in life. At the age of seven-

teen the boy ran away from home for good—the mental conflict caused by the intense love for his father and the entire absence of any return of this love being more than he felt he could bear. After weeks of hobo life, with occasional positions at manual labor, he entered the Navy, and was discharged at the end of three months for sodomy. After another period of wandering aimlessly about, trying to obtain newspaper work, and spending some disagreeable hours at home, he found himself "down and out" and joined the Army. He soon discovered that, having been dishonorably discharged from the Navy, his Army enlistment was fraudulent, and that he was liable to a prison sentence. Frightened, he sought out a non-commissioned officer, who rashly advised him to go absent without leave, go to a neighboring city to see some influential friends, and have the matter adjusted. The patient took the advice and was twice punished in three months for absence without leave. Then he deserted, was soon apprehended, and taken to the disciplinary barracks to await trial. Desperate, hardly knowing what to do, he sought to avoid the trial by feigning insanity and epilepsy. This latter move was of no avail, and in due time he found himself in the penitentiary. Having begun his malingering, he was afraid to cease, and though the physicians suspected that he was feigning insanity, they sent him here for observation.

During the first weeks of his stay he was very well behaved, and he was a faithful worker all during his residence here. Mental examination showed nothing of definitely psychopathic nature, and intelligence was normal. He showed great emotion when speaking of his sexual delinquencies, confessing to having practised all of the sexual perversions except bestiality. He showed a very natural shame when discussing his many wayward actions, and said, "I don't know what you'll think of me now, doctor." After becoming familiar with his new surroundings, it was soon observed that he tended to be mischievous, annoyed less fortunate patients, and made a general nuisance of himself to patients and attendants, by reason of his many tricks and teasing habits. He avoided physical conflicts, as a rule, and when questioned about the latter, always laid the blame on others. He showed a marked tendency to lying and exaggeration, apparently not wilful, but quite spontaneous. He was a confirmed masturbator, but showed no other sexual delinquency while here. He took considerable interest in the games and other activities of the patients, and became quite adept at handball.

He was extremely sensitive to small niceties on the part of others, and if a physician or supervisor failed to say "Good morning" to him, he would ask what he had done to make them dislike him. He constantly asked for interviews with the physician, entered complaints against the other patients, and asked how he could avoid conflicts with them. He could not be made to realize that his own mischievousness was the cause of his differences with his fellows.

During most of his stay here he assisted in one of the dining rooms. Here he was a capable worker, but a trial to his coworkers because of a tendency to assume a certain amount of authority, even over the heads of the attendants. He came into conflicts with peaceably-inclined patients over trivial matters, and often grossly insulted them. He always assumed that they were in the wrong (a habit mentioned above), yet when we talked with him in our frequent endeavors to make his relations with his fellow patients more pleasant, he would make all sorts of promises to do better, though we found them of no avail.

I have mentioned his intelligence and his deficient education; a well educated patient gave him some instruction during a part of his residence here. The boy was very anxious to become a writer and declared his intention of writing his autobiography in fictionized form. He wrote one or two crude poems, and had an article published in the Hospital paper, much to his delight, though he was afraid the material in it might be misunderstood by other patients. He used to bring his literary efforts to me for correction, and they showed a certain amount of originality of style, in spite of misspelled words and poor grammar.

Briefly stated, the boy's make-up is that of an individual of normal intelligence, capable of earning a

livelihood, but entirely incapable of keeping out of trouble. He often volunteered to me the statement that if his father had been like other fathers and given him the affection he craved, he would have been a success in the world. This is probably partly true, for his father-attachment has played no small part in his life, has been a constant stimulus to him in his efforts to do better, and he used to say that he was bound to make good just to show his father that it was in him.

The outcome of his case is doubtful. He was recently pronounced not insane by the hospital authorities, and he was taken back to prison, where it is said that he must now stand trial for malingering, since he had imitated epileptic fits and mental disease before he was sent to this institution. This seems to me a very unfortunate turn of affairs in the boy's life. He had nearly completed his present sentence, and expected to be released and go to work on a Western ranch, where the out-of-door life and clean surroundings might have had a salutary effect. If the law sees fit to punish him for this other offence, which was really a mental upset of the situation-psychosis type, a defense reaction for which he can hardly be blamed, he will again have to endure prison life, with a chance that he may develop a real psychosis, a more serious one, and become a burden on the government; whereas if they overlook the offence and free him, he may yet make something of himself. He responds at once to any show of affection, and if perchance he could come in contact with some paternal type of man who would take an interest in him, this "black sheep" might yet become one of the people who are of use to the world, instead of continuing to be—as he has been in the past—a public burden. His crimes have been the result of his inability to adjust to critical situations; he becomes panicky when such situations arise. He is inherently unstable and his father-attachment has been the source of constant mental conflict. In addition he is polymorphous perverse, and there seems little likelihood that he will ever make a lasting or comfortable adjustment.

CASE II.—Another Constitutional Inferior.—J. W., an American, aged 39 years, was sent to this institution as a Federal prisoner, while serving a sentence for representing himself as a Federal officer. On admission he was suffering with a paranoid type of psychosis, with precoc-like elements. He could not give much information about his family, but there were sufficient data to show a poor ancestry. He had less than a year of schooling and was barely able to read and write. About his childhood he could tell us but little, but we know that at the age of twelve his father began to give him beer, and his alcoholism dates from this early age. The father tried to teach the boy his trade of stone-mason, but the boy was unable to learn it. The patient has always led a wandering, irresponsible life, working at all kinds of manual labor, sometimes earning as high as five dollars a day. This was earned as a watchman on a levee. He never stayed in a place more than a few weeks, due to a wanderlust which made it impossible to settle down with any comfort. He enlisted as a volunteer during the Spanish War, and was dishonorably discharged for drunkenness at the end of six months. Since that time he has several times enlisted in the regular army, but has always been arrested for fraudulent enlistment, and served time for the offence. He states that all of these enlistments have occurred while he was under the influence of alcohol. He has been a periodic drunkard since early youth. He has led the life of a tramp, and learned the use of cocaine in a

bobo camp. While in a drunken sleep he rolled into a hobo campfire, receiving burns which badly deformed both feet.

His sexual experiences began at the age of six, when a sister, now dead, took him into a closet and tried to perform sexual intercourse with him. He is a confirmed masturbator. His first successful heterosexual experience was at fourteen years of age, with a prostitute. While he has led an active heterosexual life, he has frequently allowed himself to be used as the passive agent in homosexual acts. He admits sexual inclinations toward a half-sister, but has successfully repressed them. However he confesses that while at her home, her twelve-year-old daughter used to climb into his bed, and he was accustomed to fondling the child. He did not know whether he had ever violated her or not, but stated that this might have occurred when he was under the influence of alcohol. He has had gonorrhea and soft chancre, but not lues, so far as can be determined.

At the age of twenty-three he married a woman of doubtful character, and deserted her within three months. They were very obviously unfitted to each other. She obtained a divorce and he remarried, at the age of thirty, a woman who had led a fast life, and had an illegitimate child. His married life with her was rather happier, and he managed to lead a settled life for two years, then the wanderlust became too strong and he deserted the second wife to become a wanderer again.

While out of funds, and with no prospects of work, he forged a check and had it cashed, representing himself to a restaurant keeper as a Federal officer. He evidently did not do a very clever piece of work, for in a few hours he was under arrest, and in due time was sent to the penitentiary. As usual with him, he was intoxicated when he committed the crime, for he never violates the law when sober.

I will not go into the details of the psychosis which caused him to be sent here. It was of paranoid type, with visual and auditory hallucinations of terrifying character. Voices told him that he had scattered syphilis all over the country, and accused him of many crimes, most of which had some actual foundation in his past life. He was very hypochondriacal, depressed, and spoke in low tones. He was accessible, frank, and at times showed marked fear of his hallucinated persecutors, who threatened him with death. Syphilophobia was the most marked feature, but this was later relieved by the physicians' assurance that the Wassermann tests gave negative results. The patient had some insight into his condition, realized that his mind was not in its normal condition, said that his memory was failing and expressed a desire for aid for his mental condition. In reply to a question about his troubles he said, "*Seems like I never have been right, somehow. Everything goes against me and I can't stay satisfied with anything.*" This expressed in his crude way more insight into himself than individuals of this type usually have.

Intelligence tests showed that he was not a defective, in the intellectual sense, though allowance had to be made for his meager education. He could answer the fifteen-year-old tests of the Binet-Simon scale fairly well, also some of the adult tests, and we do not consider an individual to be a mental defective who can pass the fifteen-year-old tests, especially if he is uneducated. Memory was, on admission, grossly impaired for both recent and remote events. The psychosis gradually cleared up and he regained his normal mental state.

This man labors under strong congenital taint. A maternal aunt was insane, the mother was a consumptive, and if he were able to tell more about his family still other tainted ancestors would probably be in evidence.

In his make-up he is a very pleasant individual, sociably inclined, accessible, responding at once to any show of interest. He chose the more intelligent and refined patients as his associates and took a keen interest in everything in his environment. He wrote letters to his father, which were concisely and intelligently expressed, in spite of his poor education. He always got along remarkably well, his only conflict being with the patient mentioned in case one. He once knocked this man down after repeatedly warning him that he would do so if he did not let him alone. In this case he

was quite justified, the incident amounting really to self-defense. He was a good worker, in spite of his deformed feet, and was well liked by all his associates, being one of the few patients about whom no complaint was ever made by attendants or patients.

To casual observation J. W. is a normal individual, able to earn his own living, and quite harmless. But just as soon as he gets out into the world his alcoholic habits, which are in all probability a shield from his unpleasant mental conflicts, will return. The man is polymorphous perverse, unable to make any lasting or comfortable adjustment, because of his inherent instability. Alcohol is the only comfortable solution of his problems, and with him alcoholic indulgence means loss of his ethical sense and lapses into crime. This latter fact he himself realizes and he says that he realizes he has done wrong in the past, and would not have done so if in his right mind, but while under the influence of alcohol he gives no thought to the ethical side of crime. As might be expected, he does not realize his sexual difficulties. He is decidedly not a moral imbecile, for when sober he is honest and trustworthy, and fully appreciates the difference between right and wrong. He realizes quite fully the unfortunate blunder he has made of his life. He is unable to adjust to his difficulties unless he is under institutional care, where he is in the proper environment to make the most out of his life. Under intelligent and understanding supervision this man could be made into a useful citizen, instead of being a public burden, as he now is, and will continue to be under our present system of dealing with such individuals.

He once told me that he would like to spend the rest of his life in such an environment as this institution afforded, because he could always have the physicians and attendants to appeal to for what he wanted, and would be free from the influences which he must invariably meet when he goes into the outside world. Not that he does not desire his freedom, but he seems to realize how fruitless will be his endeavors to lead a better life. His amount of insight into himself is rather unusual, for practically every other similar case I have met attributed his mishaps and misdemeanors to environment, unfortunate circumstances, or the fault of others, and stoutly maintained himself to be quite innocent.

CASE III.—Psychopathic Constitution.—M. W., aged 39, a chemist, was sent here as a Federal prisoner, while serving a sentence of fifteen years for white slavery. I can give but a brief synopsis of his case, the records of which occupy many pages. The facts given below are for the most part fairly accurate, being partly obtained from outside sources. The patient himself is the most fluent liar I ever met, and no two of his accounts of himself agree.

He comes from heavily tainted stock. The father, aged 73, has always had a violent temper, and is insanely jealous of the mother. The father is at present suffering from senile dementia. A brother and sister are insane, the sister being a catatonic precox. One brother is alcoholic and the whole family are of decidedly nervous make-up, and subject to various physical ailments, which the patient is inclined to think are the result of congenital syphilis, although there is no definite support for this belief.

The patient's birth was normal and he was healthy during infancy and early childhood. Mentally he has always been rather above the average, and did well in school and college, where he specialized in chemistry. His senior year in college was interrupted by his enlistment as volunteer in the Spanish War, and he took special courses in chemistry on his return. He has held

good positions as a chemist, and as an officer of a mining company, earning \$1500 a year and expenses, and accumulating considerable property.

Unfortunate influences were present in his life at an early age. From his fifth to his thirteenth year, a manservant in the family used the boy as a sexual object. The boy was kept in constant fear of this man, and though his parents believed that they had stopped the practice, it continued until the boy was ill for a year at the age of thirteen, suffering from a severe attack of typhoid. These experiences of course left their mark on the mind of the growing boy, although he does not realize the part they have played in his later life.

He masturbated from his ninth to his eighteenth year. Normal sexual intercourse began at the age of fifteen, in a house of ill-fame, while on a football trip. If we were to believe the patient's own statements he has always been strongly heterosexual, although from the results of our observations, those in charge of him have always believed him to be an inherent homosexual, and that his unrecognized homosexuality has played a large part in his mental life.

During his college career he received a severe head injury, and later two other injuries of the skull, which left him unconscious for several hours. The man actually has a depressed fracture of the skull in the left parietal region, but it is difficult to believe in the light of the combined facts of the case that this fracture is responsible for his mental instability, and the series of events which led to his prison sentence and his incarceration in this hospital. He has always laid great stress on his belief that all his misdemeanors and the course of his life since leaving college were directly and solely due to his head injuries.

His family life has been far from happy. He had a strong attachment for his mother, and was her favorite child. He and his father were always at swords' points, and one of his brothers has always played a part in his family troubles, the two being enemies, whether due to a rivalry for the mother's affections or not, I am unable to say. This brother will be mentioned later in the case.

Since leaving college the patient has led a wandering life, though never a tramp, for he has always been able to obtain remunerative employment. If we take his statements as truth he has had periods of what he calls amnesia or epileptic equivalents, during which he would wander all over the United States, Alaska, and even Siberia. He would come to himself far from home and not be able to account for himself, not knowing where he was or why he had come. He has also been subject to epileptiform attacks, which we believe to have been hysterical in nature, as they practically always occur when he is in some painful situation, and he has had but two in a residence of nearly a year in this institution. I was present during one of these, which occurred after he had been telling me certain painful details of his past life. It lasted about fifteen minutes, and there was nothing about it to indicate that it was either epileptic in nature or due to his head injury. These convulsions occurred with great frequency while he was in prison, because prison life was of course an extremely painful situation for him, as he is rather refined and over-sensitive as to the material comforts of life. Since being here he has had more attention and his people have provided many delicacies and creature comforts for him, and the environment has been comfortable enough so that he has not had to seek refuge in his hysterical episodes.

The patient married a Catholic girl in 1904, by a civil ceremony, and refused to accede to her parents' wishes and be married by a Catholic priest. They lived together only four months. His accounts of why they separated are very contradictory, but I feel safe in assuming that the patient's latent homosexuality had much to do with it. He refuses to recognize this homosexual element, and I believe his boasts of numerous heterosexual experiences, as well as the white slave episode, are but an unconscious reaction against the homosexual element. He professes extreme disgust for anything except normal intercourse, and tries to give the impression that he has led an extremely active heterosexual life. This is a common reaction in homosexuals.

Previous to the episode which led to his arrest the

patient came home from Alaska to make what he believed would be his last visit to his aged mother, who he did not think would live long. He no sooner reached his parents' home than the old conflicts with the father and brother were renewed. The father caused the brother to accuse the patient of having been too intimate with the mother and said that he had seen the two in a compromising situation. (This incident has been partly corroborated by the family.) The patient was so angry at the charge that he obtained a knife with the deliberate intention of murdering his brother for the insult to the mother. A convulsion conveniently intervened, and when he recovered it was too late to carry out his plan. He obtained all the money he could, several thousand dollars, and started for Alaska, but reached only a nearby city, where he lost money, clothes, and baggage in some mysterious manner. He borrowed from a sister and started again. He arrived in San Francisco, where he became very ill and was unconscious for many weeks. (This was, in all probability, a precox episode, as he has been treated in a local sanitarium for a similar one some time ago.)

After recovering from this and while traveling in the Middle West, he became involved in his present difficulty. His accounts of this are extremely conflicting. While in a small town, he one night picked up a woman on the street, believing her a common prostitute. He was under the influence of alcohol at the time. They spent a night at a hotel, and while he was asleep the woman searched his pockets and obtained the address to which he was going. Shortly after arriving there he received a letter from the woman saying she was pregnant by him and asking his advice and help. He made a trip to see her and found she had lied. The upshot of the matter, however, was that he allowed her to travel about with him for a time, though trying to bribe her to leave him. During their stay in a mid-Western city, they became acquainted with a young waitress in a restaurant. Here the sequence of events is not clear, but the waitress went with them when they left the city. The girl's mother and sweetheart followed them and caused the arrest of the patient and his companion on the charge of seduction. This charge failed, also a second charge for statutory rape. He was then charged with violation of the Mann Act. Of his trial he has told many conflicting stories. His brother appeared as a witness for the prosecution, and swore that the patient was a sexual degenerate. The patient's companion turned State's evidence and testified that he had hypnotized her so that she was powerless to resist him; she also testified that he had performed homosexual acts in the lodge room. The patient says that he himself was so confused as not to know what he said or did at the trial. I have since learned that it was definitely proven that he really committed one of the most flagrant white slave crimes which has been brought to light since this law went into effect.

During the six months he was at Fort Leavenworth before coming here he was frequently violent and had numerous hystero-epileptic seizures. He complained of constant headache and vertigo, with epistaxis and projectile vomiting (symptoms which might be referable to the depressed fracture). He was told he had a blood clot on the brain and needed an operation.

On admission here he was hypochondriacal and complained constantly of headaches and vertigo. An x-ray of the skull at the Army Medical School was negative. It is noteworthy that after the lumbar puncture was performed these headaches disappeared and now return but occasionally and with decreased intensity. Our study of him here shows him to be decidedly hypochondriacal, and unable to stand even slight discomforts without much complaining. He is rather paranoid, being apt to translate any untoward incident as deliberately planned to annoy him. He complains, in letters to relatives, of his treatment here, although he is given every possible privilege, receives special food ordered for him by relatives, and has more luxuries than any other patient in this department.

He is decidedly intelligent, reads the better periodicals and books, and his opinions on current events are quite worth listening to. He is sociable, associates with only the better class of patients, and is usually good humored and fond of a joke. He is refined in appearance and habits, and would make a good impression in

any society. I have never been able to decide whether his untruthfulness is normal or pathological. He lies only to evade giving information about himself and when proven to be lying he shows no shame, but proceeds to repeat the offence in order to cover the default. He reacts in an exaggerated manner to any stimulus, and thus makes himself rather a nuisance at times. He is very neurotic, complains frequently of trivial ailments, and is constantly asking for medication of one kind or another.

Some of his paranoid reactions amount almost to delusions of persecution. He is a Mason and believes that three of his fraternity "have it in for him," and cites specific instances thereto—instances which might seem convincing had not the patient deviated from the truth so often in other matters.

One matter which troubles him considerably is the fact that he is considered a sexual pervert. In conversations with me he has frequently mentioned this and gone to much length in trying to convince me that he is strongly heterosexual and that he had never had the slightest tendency toward homosexuality. All of this, as well as his paranoid reactions, are, to my mind, a defense reaction against his homosexual trends. And since in his early years, in the period of psychosexual development, he was for so many years the object of homosexual practices, it is only reasonable to suppose that his psychosexual development ceased at the homosexual level. His inner conscience recognizes the fact, but the psychic censor refuses to let it come into outer consciousness. Hints of his homosexuality do penetrate and are met by defense mechanisms—as for example, the desire to prove to us that he is heterosexual, the disgust when sexual perversions are discussed, etc.

This man, then, is a constitutional psychopath. With a strong congenital taint he came into the world unfitted to react to the critical situations he has had to meet. Highly intelligent, efficient in his line of work, he is yet unable to make a lasting adjustment because of his inherent instability. What are we to do with this man? When his sentence expires he will be about forty years old; it takes a man of stable make-up to start at such an age and make anything of his life. He refuses to try to have any real insight into himself and his paranoid nature makes him think of himself as a martyr suffering from the malice of people who persecute him without any cause. And of course his abilities are going to waste as long as he is in confinement. He is able to support himself well, but is forced to a life of idleness. When he is released he is suddenly thrust into a situation where he must adjust to sterner problems than ever before, and the result is very doubtful. Is this man responsible? Yes, and no. He is not lacking in intelligence or ethical sense. He is not to blame for his inherent instability, the real basis of his inability to live as society demands. I must confess that I can make no suggestion as to the proper disposition of the case.

CASE IV.—Sexual Perversion; Constitutional Inferiority.—F. C., aged 23, was arrested in a public park, having been detected in a perverted sexual assault on a little girl. In order to escape the disgrace and publicity of a trial, his brother managed to have him committed to this institution. To aid in this committal, the patient feigned confusion and dementia. An experienced observer made a diagnosis of low-grade imbecility, though our observations here have since shown him to be of normal intelligence. In the family history we find that the mother is of nervous make-up, and had a brief mental upset, mild in character, at the time of her marriage. I have had occasion to interview one of the patient's brothers, and he gave the impression of being of precox make-up.

The patient's birth, infancy, and childhood were apparently uneventful. He received a moderately good

education and had no difficulty with his studies. He has worked at various occupations, the last one being as motorman on an electric car line. He is said to have been discharged for having failed to register fares properly. However, those under whom he worked considered him to be an efficient worker. He is a member of the Catholic Church and always attended regularly. He has always been considered by his friends to be a model young man. His home life has been happy as far as can be determined.

His initiation into the knowledge of sex was, as in the case of so many boys, obtained from other boys, when he was about fourteen. He avers that he was told about normal sexual intercourse, but not about any of the perversions. When he was seventeen years old, in company with some other boys, he visited a house of prostitution. It was his first contact with women in a sexual way. To the surprise of the woman he began to perform cunnilingus. Believing that the patient was ignorant the woman tried to show him how to perform normal intercourse, but he told her he had no desire for it. The perversion seemed to be instinctive. He had never been told about any sex perversion and claims never to have had any previous experiences which would lead him to perform cunnilingus. He continued the practice until the segregated district was abolished. Since then he has experienced much difficulty in finding women who would submit to his abnormal desires. At intervals of about a month he has marked sexual desire, accompanied by a feeling of heaviness in the head. This feeling is relieved if he can perform the perversion. When he cannot find a woman he often obtains sexual pleasure by contact with a woman's undergarments to his mouth. On one occasion he sent a letter to a Jewish merchant, telling him to hang his daughter's undergarments in front of his house, or his store would be burned. He was apprehended, explained his perversion to the police chief, and was put on probation. Realizing the abnormal nature of his sexual instincts, he has on a few occasions attempted normal intercourse, but has never been able to accomplish it.

He does not care for the company of the opposite sex and has never had a sweetheart. He is rather seclusive, preferring to spend his time reading. However, during his stay in this institution, he has developed a tendency to spend much time in the company of some of the poorer class of patients, chumming with those who are uneducated and degenerate, in preference to the educated and better class. In his day dreams, if we may believe his own statement, he likes to picture himself as being normal sexually and as a married man with children. He is rather fond of children, but would prefer to have them without having a wife, if possible. He can not bring himself to care for women, except as objects for indulgence of his perversions.

When admitted the patient was quiet, orderly, polite, and obedient to suggestions. He asserted that his sexual perversion was a constant source of worry, that he felt himself a degenerate, and eagerly accepted the examiner's suggestion that psychoanalysis be tried in his case, saying that he would cooperate to the best of his ability. However, he did not live up to his promises, and unfortunately soon had a negative transfer toward the examiner, due to a paranoid interpretation which he put on some insignificant occurrence in which the examiner figured innocently. From this time he was distinctly inimical in attitude for several months. He then came to the examiner and asked why the latter had it in for him, and proffered apologies and renewal of friendly relations. He was not sincere in this offer, though, and the examiner has never been able to get in good touch with him.

Mentally, the patient is of average intelligence, and shows no disorders of conduct. He was rather emotional at the time of admission, but at the present time he is adapting well to his situation. He has shown nothing which could be interpreted as belonging to a mental disturbance, with the exception of a somewhat paranoid attitude toward the officers of the institution. This is very slight in degree and can hardly be classed as being delusional.

Physically, he shows a number of stigmata of degeneration.

There is nothing in the examination of this man to point to mental instability if we rely solely on his record since in the institution. However, when we take his past life into consideration it is not difficult to see that his sexual twist is one phase of his illy-balanced mental make-up. The discharge from the car company for theft, the threat to burn a man's house if he could not obtain the object he sought, the tendency to seclusiveness which he showed before coming here, all point to a lack of stability in mental make-up. In addition, he is impulsive, and unable to resist the desire to indulge in his perverted practices. The man is not insane, from the ordinary standpoint, yet he is a dangerous individual to be at large, because of likelihood of further attacks on girls. What is to be done with him? This case was recently brought before the hospital staff for a decision as to its disposal, and the unanimous opinion was that he should be kept in confinement here; that while he is not insane, the nature of his crime was such as to make confinement imperative.

CASE V.—Constitutional Inferiority.—L. N., a young Greek of 21, was arrested on a charge of indecent exposure. While awaiting a hearing he became frightened, being unable to speak English intelligibly, and had a brief prison psychosis of the dementia precox type, recovering rapidly after being sent to this institution. On account of his extremely limited knowledge of English it was impossible to make a satisfactory study of his life. As far as can be learned, his childhood was quite normal. He ran away from home and led a wandering life for several years, but always worked and saved his money. His habits were good, and until he reached this country he never had any trouble with the law. He was accidentally left in this country by failing to sail with a ship on which he had been working. He has been in the United States about a year, working in New York and Washington, and seems to have been fairly contented and to have been satisfactory to his employers.

His three offenses against the law seem to have been due to an absolute ignorance of our laws and customs, rather than to any intentional disregard of them. While near a small town he bathed in a small stream without a bathing suit and was arrested and fined. A week before his present arrest he was on the street, when he felt a desire to micturate. Knowing nothing about public convenience stations, he turned into a small alley and satisfied nature's demands. He knew no wrong in the act, for it did not seem at all unusual to him. He was seen by a policeman and warned against repeating the offense. A week later, coming out of a public convenience station, he carelessly neglected to fasten one trouser button. He was seen by the same policeman who saw him before and arrested on a charge of indecent exposure. He had not the slightest idea why he was arrested and saw in it only rank, malicious injustice.

When he was placed in jail to await trial, the boy became extremely frightened and confused, wept, and finally became angry. Then he refused to keep on his clothes or to eat. This caused the officials to suspect mental disease, and he was examined by a psychiatrist. He told the latter of a vivid dream of seeing his mother and, on account of the patient's broken English, the psychiatrist put this down as a visual hallucination.

On admission to this institution the boy presented the picture of a mild depression, weeping frequently, and once threatening suicide. Aside from the depression, which was distinctly pathological, the boy showed no other psychopathic symptoms except a slowness of adaptation to his surroundings.

Physically, the patient is short of stature, but well developed. His head is dolichocephalic, and the facies rather repellent, though it is difficult to say just what particular feature is unpleasant. At first sight the boy gives one the impression of being both defective and degenerate. However, he is of normal intelligence, as judged by the Binet-Simon test, and no evidence of

degeneracy has been observed to date. A few days after his arrival a sexual pervert entered the patient's room early one morning and frightened the boy into permitting fellatio. The patient came to the physician in considerable distress, asking that further attacks be prevented. However, he showed no abnormal reaction to the incident. During the first few days of his stay he showed fear of his surroundings and was slow in adapting himself to his environment. He frequently approached the physician, saying, "I good boy; I no done nothing. Please, mister doctor, let me out." He could not understand the reason for his confinement in the institution and, although it was explained to him many times, he repeated his request for liberty. His reaction to his situation is rather childish. If he cannot obtain what he wants he cries, then becomes angry.

Of course considerable allowance must be made for his lack of knowledge of American customs and the English language. Also, he comes of a somewhat temperamental race. But his difficulty in adaptation is pathological, as is his infantile reaction to unpleasant situations. He has always managed to make a normal reaction to his environment until confronted by the situation which brought him here. This was more than he could meet and the prison psychosis was the result. He is not a mental defective, has previously reacted normally to the ordinary every-day situations, but is distinctly lacking in adaptability to the more serious situations. This man is an alien and will probably be deported as an undesirable.

CASE VI.—Homosexuality.—W. B., a soldier, aged 30 years, was sent to military prison for desertion. While there, it was observed that he was of paranoid make-up, and inclined to be excessively self-sufficient. He was accordingly sent to us for observation. Unfortunately our study of him has not been as satisfactory as we wished, so his case will be rather inadequately presented.

Both maternal grandparents died of tuberculosis. His father died of a "nervous breakdown." Otherwise no psychopathic determinants are elicited. The patient's birth and early development were normal and he had a moderately good education. At the age of twelve he was thrown on his own resources by the death of his parents. Most of his life he has done electrical work, and has had some good positions, the best one being as superintendent of line construction at \$140 per month. In 1908, during a hard-luck period, he enlisted in the army and received an excellent discharge at the end of his first enlistment. He reenlisted, transferred to a different branch of the service, and later bought out his discharge to take a paying position in civil life. After a time he again reenlisted and was in the third enlistment when he became involved in his present difficulty.

As a boy his family life was happy and he got along well with his playmates. As a rule, he has been a hard worker and of exemplary habits. In one of his enlistments he was in a rather bad company of men and as a result of this association, he says, he was a heavy drinker for about two years.

Sexual life has been normal, and he has repressed his sexual desires to a considerable extent, because he believes in moderation in such things. He tries to give the impression that he has not been given to thoughts of sexual matters, and has put them out of his mind as much as possible. He was married about a year before his present trouble began. It is noteworthy that, although he had a good record as a soldier, he violated one of the unwritten rules of the service, which says that when a soldier marries he shall obtain the consent of his superior officer. He believes that this caused him to incur the dislike of his superior officer. He claims that his married life has been very happy. His wife became pregnant a few months after marriage and then the patient's troubles began. His wife was not strong and her physician told her that she ought to spend most of her

pregnancy in a hospital. The patient was getting but \$25 per month, and he estimated that it would cost this amount per week to put his wife in the hospital. Immediately he became panicky and, instead of calmly reasoning out the proper course to pursue, he acted on the impulse of the moment and deserted. He says that he did this in order to get a paying position in order that his wife might have proper care.

He was soon apprehended, tried, and sentenced to three years. He had not been long in confinement before it was observed that he was of markedly paranoid make-up. Also he was too self-sufficient, and thought that he could do things better than anyone else. He says that in an interview with a medical officer, the latter made impertinent inquiries about his domestic life, and finally called his wife a prostitute. This story he has steadfastly clung to since being here. He says that his mail was help up and censored. This is quite likely true, but the officials were within their rights. There were a number of small incidents upon which the patient put a paranoid interpretation. He has thoroughly convinced his wife that he has been wrongly treated.

Since admission here he has always been quiet, a good worker, and spends his spare time in the study of electricity. He is sociable and agreeable, and enjoys the diversions which the patients have. He gives the impression of being extremely careful to avoid giving expression to anything which might be considered pathological. He has made the best of his situation and is, in fact, rather too self-satisfied. He is somewhat suspicious and has devised a scheme of numbering his letters to his wife to find out whether they all reach her or not. He believes that the medical officer referred to above had it in for him, and sent him here in order to deprive him of his chance for freedom.

He writes frequently to his wife, and his letters are a curious combination of endearments and anxious inquiries, with definite orders as to how she shall conduct herself in this, that, or the other matter. Practically the only thing he allows her to use her own judgment in is the choice of her clothes. When she does not do things exactly as he likes he scolds her and says she does not obey him as a true wife should. In the next paragraph he tells how much he loves her and misses her and the baby.

Mental examination shows that his intelligence is normal. There are no true delusions of persecution. He has put a paranoid interpretation upon numerous incidents, and believes himself a martyr to the whim of a superior. With the martyr's attitude is combined the exaggerated self-sufficiency, and the tendency to take everything into his own hands. Evidently it is painful to him to have to submit to the judgments of others, and his wife is the one who must suffer from his wish to be his own master, all-sufficient, at once lover and master.

What was the psychology of this man's desertion? Why should a previously good soldier disregard the courtesies of the service when he married, and then desert? To my mind, he is a latent homosexual and the marriage tie has therefore been unsatisfactory. He cannot acknowledge this to himself, and the reaction is a desperate attempt to convince himself that he *does* love his wife, and he proves it to himself by breaking the law, making a deliberate sacrifice of his military career. His period of alcoholic addiction may be explained by the fact that in the bad company he was then in there was unusual material to bring out the latent homosexuality, and it was compensated for by drink. Again his tendency to repress heterosexual desires speaks for the same homosexual trend. This may seem like far-fetched reasoning, but it is to me a satisfactory explanation of an otherwise inexplicable case. The man has hitherto compensated well, but marriage and its responsibilities were too much for the mental balance to withstand, and the idea of strengthening the marriage ties by paternity was the last straw. And

since, when he gains his freedom, he must face the same situation, his future seems doubtful as to mental stability.

CASE VIII.—*Constitutional Psychopathy; Homosexuality.*—A. R., a soldier, was arrested on a charge of sodomy, and sentenced to two and one-half years in prison. While serving sentence he became hysterical, had wandering delusions, brief in character, showed great effeminacy, and openly proposed homosexual acts to the attendants. On account of his behavior he was sent to this institution for observation.

His family history is negative. Birth was normal, but he was a weak infant and never very strong in his earlier years. His schooling began at the age of four, with home instruction, and he attended public schools from his seventh to his eleventh year. He then received instruction under private tutors until his eighteenth year, studying a varied program of scientific subjects, theology, philosophy, and the like. He then felt a desire to "start out for himself," believing he should no longer depend on his father for support. This, in spite of the fact that he was a dreamer, impractical, whose chief object in life was reading and study. He did not care for the games and sports of his companions, but preferred to read or play the piano. Of his family life he has told us but little. He says it was happy, but prefers not to discuss it.

When the subject of his sexual life was broached, the patient launched into a long argument, the burden of which was that he is strongly heterosexual and has no homosexual tendencies. He put forth the facts of his sexual life, and proved (to his own satisfaction, at least) that he has always been extremely fond of the opposite sex, and a gay Lothario. He boasted of having lived with a girl for three years, as man and wife. He understands the subject of sexual perversions in a superficial way, and used this knowledge as part of his argument. He stated that he had a double positive Wassermann in 1912, but says he had not had a luetic infection to his knowledge. However, the fact of having the positive test seemed to give him satisfaction, and to be an added proof of his virility. He recognizes the fact that he is considered to be homosexual, yet fails to understand what there is about him to give the impression.

In appearance he is very effeminate. The features are feminine and the hair, parted primly in the middle, accentuates this. He uses feminine expressions, such as "Goodness me," "My gracious goodness" and the like, forming his words with a prim preciseness and speaking in soft tones. His gestures are also effeminate. So marked is this effeminacy that some of the patients remarked about it, and one of them, who had known him before, stated, "He is a disgusting degenerate." He is avoided by many of the patients on this account.

He had a good record in the army previous to his crime. He is an expert stenographer and has testimonials showing that he was a valuable clerical worker. His account of his present trouble is not convincing. He denies absolutely that there was any ground for the charge of sodomy, saying that it was a trumped-up affair by men of his company who considered him a snob because he did not associate with them, and drink, and patronize prostitutes. However, he received a sentence of two and one-half years, indicating that there was some ground for the charge. In prison, according to the records which accompanied him, he became emotional, had wandering delusions, was more effeminate than ever, and proposed homosexual acts to the attendants. He denies all of this at present, and it is quite likely that he has forgotten it, that is to say, it has been relegated to the realm of the unconscious, with his other disagreeable and repressed mental processes. During his stay here he has spent his time reading scientific works, and writing poetry. He has a large number of poems, none of them showing real merit, and several of them giving unmistakable homosexual symbolism.

Here we have a latent homosexual, in whom a superficial knowledge of the sexual perversions has helped to repress tendencies which were very near

the surface. The desire to show himself independent, choosing the life of a soldier (symbolic of virility), exaggerated attention to heterosexual life, as well as the frank homosexual outbursts in his psychosis, all point to a striving to overcome the homosexual element, which he probably really recognizes, but will not acknowledge to others. His insight into homosexuality was not sufficient to permit a strong compensation, as was manifested by his homosexual advances while in his psychosis. I have purposely omitted many of the details of this man's history, as irrelevant to the subject in hand. He illustrates the type of homosexual which is not so difficult to diagnose, for it is written in his physical make-up, in his speech, and in his reactions under stress.

Relieved of the strain of prison life, free from the environment of the barracks, where he can return to his seclusive, studious habits, he may be able to compensate comfortably for a time, and with his training in stenography can earn his living, giving him the feeling of self-sufficiency, and permitting him to resume his life in the world. Just how long he will be comfortable is difficult to say, for we do not know what situations will arise to stir up the fires which will always smoulder in the depths of the unconscious. He is engaged to be married, and if he does undertake the responsibilities of married life there is likely to be a real disaster. Incidentally, the description he gives of his fiancée indicates that she too may be a homosexual. He has been advised not to marry, but with the exaggerated self-confidence of the psychopath he pooh-poohs the advice, and will probably enter boldly into the married state at his first opportunity, in a final attempt to convince the world and himself of his heterosexuality.

Conclusions.—In summing up briefly the characteristics of the borderland mental cases, referring especially to the criminal type, we note that

1. They usually show poor heredity.
2. They may or may not show mental peculiarities during childhood.
3. They may develop a normal intelligence, and may show special aptitudes for certain lines of work, but fail to accomplish any real or lasting success because of lack of perseverance, restlessness, faulty judgment, impulsiveness, and inability to plan clearly, or to carry through their plans to a definite end.
4. In uncomfortable mental situations they are unable to react properly, and the result is apt to be a mental disturbance or a conflict with the law.
5. This class includes the moral imbeciles, who break the law because they are unable to appreciate the difference between right and wrong. On the other hand, these individuals may have a normal ethical sense, but in confusion or panic, during some uncomfortable situation, may come into conflict with the law because they see no other way out. Their crimes may be traced to the outcome of some psychic difficulty, being a result in the course of an attempted solution of the problem.
6. These individuals have a tendency to be excessively self-sufficient, a compensation for their real inefficiency.
7. They have little or no insight into themselves, and believe themselves the victims of unfortunate circumstances, or of the malice of others.

8. In comfortable environments, free from mental stress, they present a more or less normal picture. However, the trained observer will note lack of real efficiency, poor judgment, childish reactions to many situations, exaggerated self-esteem, and absence of perseverance.

9. They exist comfortably only when under supervision, with absence of mental strain. Under such circumstances they may lead comparatively efficient lives.

THE SURGICAL TREATMENT OF CANCER.*

By H. J. BOLDT, M.D., F.A.C.S.

NEW YORK.

THE surgical treatment of cancer from the standpoint of the gynecologist is limited in comparison with the treatment that comes within the province of the general surgeon. Cancers of the uterus are our most frequent cases, and, therefore, it is in this form that I will discuss briefly.

It is our endeavor, as well as our duty to cure permanently, if possible, all patients who may entrust themselves to our care. But we can do this only when the cancer is still a local disease and when we are afforded an opportunity to operate at an early stage and well away from malignant invasion. If the malignant condition has passed beyond the uterus the result must necessarily be doubtful.

The greater number of gynecologists have relegated vaginal operation for uterine cancer to the past, because the percentum of permanent cures is less than when a radical abdominal operation is done. And yet, there are conditions which undoubtedly make a vaginal operation preferable. If the patient be an obese woman and the disease is still in its incipency no doubt exists but that we get a lower primary mortality and an equally high percentum of permanent cures. Particularly is this so when one does the operation as advised by Schauta, in which the ureters are isolated and the uterine arteries ligated before attempting to extirpate the uterus, so as to make possible the excision of a large part of the parametria. The incision devised by Schuchardt is, however, always necessary to accomplish this.

To eliminate, as far as feasible, the chance of transplantation cancer occurring, it is advisable rapidly to curette with a sharp spoon all readily breaking down structure and thoroughly to cauterize the crater with a hot iron before beginning the operative work of extirpation.

There are still many surgeons who believe that a larger number of permanent cures may be obtained if the extirpation is done with a galvano-cautery. While I have used that method my experience is limited to too small a number to express an opinion on the superior merit. If one uses

*Part of a Symposium on The Treatment of Cancer read by invitation at a meeting of the Eastern Medical Society.

a cautery the current should not be turned on until the cautery knife is in contact with the tissues to be cut, since though the knife be only at a degree of low red heat, it will cause bleeding when it is brought in contact with vascular structures. But if applied cold and then brought to the proper degree of heat, the vessels shrivel before they are cut. This holds good also whenever one takes off the cautery knife for the purpose of changing its position. A description of technic is superfluous at this time. Likewise the several other methods of vaginal operation for cancer, as the clamp method and the uterus enucleation, as devised by a Chicago surgeon, require no mention, since they are not adequate to bring about a satisfactory result.

The surgical therapy considered now as acceptable when the cancer has not advanced too far for radical operation, is the abdominal method made popular by Wertheim and practised by leading modern surgeons. Since W. Alexander Freund did his first premeditated operation by the abdominal route in 1878, which was a simple pan-hysterectomy, the technic has undergone decided changes. We must not fail to give credit, however, to the excellent work done by our American surgeons, Clark of Philadelphia, and Riess of Chicago, who worked out proper technic even before Wertheim published his work, so that really to Americans belongs the distinction of being pathfinders. Without pelvic elevation, however, as devised by Trendelenburg, the proper technic would be almost impossible.

The removal of the uterus, adnexa, extensive removal of the parametria, accessible pelvic and iliac glands, and the upper part of the vagina; particularly if it be cancer of the vaginal part of the cervix, are prerequisite to success.

If the cancer occurs during the usual cancer age, say later than the age of 45 years, we can count on about 50 per cent. permanent recoveries; provided the disease has not progressed beyond a readily operable condition, and if the operation be properly done. The rule is that the younger the patient the less chance of permanent cure. The few patients that I have operated below the age of thirty years have all died of recurrence.

Regarding cancer of the body of the uterus, compared with cancer of the cervix, it may be said that the prognosis for permanent cure is better in corporal cancer.

Some surgeons maintain that in corporal cancer one should also always do an abdominal operation. For me this holds good only in instances of patients in whom the uterus is considerably enlarged, so that we have reason to believe that the malignant neoplasm has made considerable progress and that there is danger of mutilation of the uterus and soiling of the field of work with cancer elements in case one does a vaginal hysterectomy. In early cases of women with a roomy vagina and a small uterus, the operation should be done per vaginam, and, judging from my personal experience, the results are equally satisfactory, with a lesser risk of primary mortality.

What is said of cancer of the uterus holds good for all cancers of other structures that come in the domain of the gynecologic surgeon as to per-

manent curability by operation. Unfortunately the diagnosis of intrapelvic and intraabdominal cancer is not so readily made as is the case in uterine cancer. Consequently the mortality is greater, though it has been my good fortune to cure permanently several instances of medullary cancer of the ovary, which were not diagnosed as such before operation. So long as the peritoneal covering has not been broken through by the malignant disease we have reason to hope for as good a permanent cure as is the case with early uterine cancer. This consideration leads me to say that all pelvic tumors, all abdominal tumors, should be operated upon at the earliest possible moment unless too far advanced for operation, and even in many of these seemingly advanced cases an exploratory operation is advisable, because occasionally it occurs that we give relief if not permanent cure.

Primary cancer of the vagina is seldom met with in a still sufficiently early stage for a satisfactory radical operation. I have not seen any that were cured.

A most important measure should not be lost sight of, namely: Retain all patients operated upon for cancer under observation for several years, and on the first indication of recurrence reoperate. An excellent illustration for the validity of this assertion is the case of a patient 52 years old upon whom an exceptionally extensive radical operation was done for the removal of a "border-line" cancer of the cervix, during which it was deemed safest to resect a part of the ureter and reimplant it into the bladder. The first operation was done on June 1, 1914. I reexamined the patient every month. The latter part of May, 1915, by rectovaginal examination a small nodule, not larger than a hempseed, was discovered in the pelvis. In a month it had increased in size to that of a pea. The patient was told on the occasion of my first discovery what I suspected and I had no difficulty to induce her to consent to a second operation. This was done July 19, and by the pathologist's report the diagnosis was correct. So far there has been no recurrence. The patient is reexamined once every second month. A careful search throughout the pelvis at the time of the second operation failed to find any other lymphatic or glandular enlargement.

We shall now consider briefly what may be done in a palliative surgical way for patients too far advanced for radical operation. The subject may be summarized in a few words. Nothing has given me so much satisfaction as thorough cauterization with a galvanocautery, employing high degrees of heat for the purpose. But it must not be thought that every patient too far advanced for radical operation can still be satisfactorily cauterized. Such is not the case; some of these unfortunate women are past the palliative surgical intervention. Radium and x-ray treatment have occasionally given much relief.

Cure of Veronal Habit.—Fog successfully treated a veronal addict, who had become much debilitated from the habitual use of the drug, with gradual withdrawal and powders of antipyrin salicylate.—*El Siglo Médico*.

THE DIAGNOSTIC SIGNIFICANCE OF BLEEDING FROM THE RECTUM.

By ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

DEPUTY SURGEON, DISEASES OF THE RECTUM, O.P.O., NEW YORK HOSPITAL; CLINICAL ASSISTANT, DISEASES OF THE RECTUM, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING, HOME OF THE DAUGHTERS OF JACOB.

THERE are few conditions which give the physician more worry and uneasiness than bleeding from the bowel, even when the reason for it is perfectly clear; when there is any doubt about the source and causation of it, its occurrence is of very serious concern to both patient and doctor. Patients may regard other symptoms (outside of such as give rise to much pain) with an easy tolerance, but the appearance of blood, coming from an organ from which it is not seen in health, is an alarming event, and arrests instant attention. Fortunately nature has implanted in every living thing an instinctive fear and dread of certain physical signs, whose presence is grave enough, if disregarded, to lead to the extinction of the individual. A sudden gush of blood quickly arouses emotions which mobilize every faculty to secure the safety of the sufferer without any unnecessary loss of time. It was a subconscious recognition of this, and no mere idle fancy, which caused the very color of red blood to have been universally adopted to designate danger—loss of blood and loss of life go hand in hand.

A systematic investigation of a patient who loses blood by the rectum must begin with a careful history, which should emphasize the age, occupation, past or present illnesses or operations, habits, presence or absence of protrusion or pain, and any possible loss of weight. Some of these may appear trivial to the casual observer, but they often point significantly to the seat of the trouble, or contain the thread which unravels a puzzling problem. These are to be followed by inquiries into the character of the bleeding, the length of time it has lasted, its relation to defecation, the relative quantities lost, whether expelled pure or mixed with pathological discharges, and lastly by a physical examination of the patient, which must include a searching local exploration of the parts.

It is good practice before starting, to bring in mind the various conditions in which bleeding from the rectum may be met, with a general idea of their importance and frequency. The following classification, though far from perfect, has been adopted by the writer in the hope that it will simplify the problem:

A. SURGICAL.

(a) Local Conditions Not Acutely Surgical.

1. Hemorrhoids, all forms except the external.
2. Ulcerations: (a) Simple; (b) specific—from tuberculosis, syphilis, gonorrhea, various types of dysentery (amebic, Shiga bacillus, Flexner-Lewis).
3. Proctitis, proctocolitis, enterocolitis, simple and specific.
4. Tumors: Benign (Fibromata, Lipomata, etc., various pedunculated tumors), and malignant (carcinoma, papilloma, multiple polyposis, sarcoma).
5. Stricture, specific, non-specific.
6. Procidentia.
7. Fissure.

8. Cryptitis.
9. Helminthiasis.
10. Diverticula.
11. Gastric or duodenal ulcer.
12. Impaction.
13. Chronic constipation (sometimes).

(b) *Local Conditions Acutely Surgical.*

1. Foreign body.
2. Volvulus.
3. Invagination.
4. Strangulated hernia.
5. Portal or mesenteric thrombosis.
6. Typhoid fever.
7. Appendicitis.
8. Rupture of aneurysm.
9. Postoperative bleeding, following operations on rectum or colon.
10. Abscess.

B. MEDICAL.

(a) *Mechanical.*

1. Hepatic disease.
2. Chronic nephritis.
3. Cardiac decompensation.
4. Arteriosclerosis and conditions accompanied by high blood pressure.

(b) *Defective Blood States.*

1. Hemophilia.
2. Purpura.
3. Leucemia.
4. Pernicious anemia.
5. Scorbutus.
6. Icterus.

(c) *Toxic.*

From without: Poisoning by arsenic, mercury, phosphorus, sulphureted hydrogen, nitrobenzene, etc.

From within: Scarlet fever, yellow fever, cholera, malaria, septicemia, pyemia.

It would be manifestly impossible within the limits of this paper to take up in detail all the various causes of hemorrhage from the bowel, with their points of differential diagnosis; we shall confine ourselves mainly to such of them as originate in local pathological conditions of the rectum and lower colon, leaving the others in hands more competent to deal with them.

In making a critical analysis of factors which enter into rectal bleeding, one thing which stands out at once is that the causes differ widely with the age of the individual. Infants and older children bleed from prolapse, various forms of enteritis and colitis, fissure, solitary polyp, foreign body, including intestinal parasites, traumatism, invagination, but rarely from hemorrhoids, stricture, or malignant conditions. Out of 180 cases of hemorrhoids which came under the writer's observation within a definite period, only two were in children, two and a half and four years old respectively. Stricture in children arises frequently from a developmental fault, failure of the mesodermal tissue which separates the caudal extremity of the hind gut and proctodeum to become absorbed, and the persistence of a membrane between the two, partial or complete. Malignancy must not be lost sight of; though very rare in children, it does occur.¹ On the other hand, the most frequent cause

in adults is hemorrhoids, followed by the various forms of ulceration, fissure, carcinoma, stricture, etc. In 141 cases of rectal bleeding investigated by the writer in the Rectal Clinic of the New York Hospital, on the Division of Dr. E. H. Pool, eighty-one were found to have been caused by hemorrhoids, fifteen by ulceration, eleven by fissure, eight by carcinoma, six by stricture, four by abscess, two by procidentia, two by multiple polyposis, one by intestinal parasites, one by foreign body, one by fecal impaction, and nine in which no rectal pathology was discoverable. With the approach of the fourth decade rectal bleeding assumes a graver significance on account of the possibility of malignancy, which does not diminish until the seventh decade, beyond which malignant tumors of the rectum are decidedly rare. In our series of eight cases, four were under thirty-five, only one above sixty. Out of 157 patients examined on the service of the Home of the Daughters of Jacob, between the ages of sixty-five and 107, during the past three years, there were only two which had tumors of the rectum suspected of being malignant.

Occupation.—Bleeding from the bowel as related to occupation is a question which may come up in operatives in mercury, arsenic, phosphorus, etc., on account of the liability of these agents to become absorbed and cause catarrhal conditions of the bowel; indirectly in workers in lead who are predisposed to chronic constipation and fecal impaction; in employees of breweries or distilleries and others whose habits and environment predispose to hepatic and cardiovascular disease.

Illness, past or present, has a decided bearing on the possibility of bleeding from the rectum, as may be readily learned by looking over the list of constitutional diseases in which it may occur. Some of these have a wide distribution, notably tuberculosis, syphilis, and hepatic disease. Primary tuberculosis of the intestine is very rare,² even denied by some (Von Leube, Klebs³), but secondary infection from the lungs is quite common; in 1,230 autopsies in the Royal Victorian Hospital, but two gave evidence of primary involvement, while 285 were secondary to tuberculosis elsewhere. Syphilis may involve the lower portion of the intestinal tract as chancre, or in its secondary and tertiary manifestations as mucous patches, condylomata, fissures, ulcers, proctitis or coloproctitis, gummata, and strictures, besides congenital lesions, principally of the anal portions, which give rise to ulcerations. Of these, chancres and gummata are infrequent, the others fairly common. In an active dispensary service only two gummata and but one chancre were encountered by the writer during the last three years, and the bleeding from these was negligible. Hepatic disease may be set down as a fruitful source of rectal bleeding because of its mechanical and other effects in bringing about pathological conditions of the rectum.

Habits.—Alcoholism being a common cause of cirrhosis and disease of the blood-vessels, is responsible for congestions which may be the starting point of ulcerations and bleeding. Improper food, unhygienic habits, the frequent use of purgative medicines may have the same effect, insofar as they have a tendency to produce proctitis.

Protrusion.—There is an intimate association

between protrusion and bleeding; when the bowel or portions of it loses its normal habitat, it becomes exposed to ulceration from friction, interference with its nutrition, and change in its secretions. The most frequent pathological lesions under this head are, internal hemorrhoids, procidentia, mucous polyps, malignant tumors of the lower rectum which project through the anus, cysts, and various pedunculated tumors.

Pain.—Patients who have lesions in the lower rectal segment have pain whether they bleed or not; in those whose disease is high up the bleeding may be entirely painless, at least until there are secondary effects on neighboring tissues or organs. An acute fissure will bleed but little, but may be exceedingly painful, while carcinoma of the rectal ampulla bleeds profusely almost from its inception, but is not generally at that stage accompanied by much pain. Because of secondary infection, progressive ulceration, the accumulation of mucus, pus, and necrotic slough, and the irritation of the bowel, which seeks to rid itself of this foreign material, there is frequent and painful desire to evacuate the intestinal contents, which may be said to be characteristic of malignant growths of the distal colon, but is never a part of the clinical picture in bleeding from hemorrhoids or other benign lesions, no matter how profuse the bleeding. It is not uncommon to find that some of these patients have as many as fifteen to twenty bowel movements in twenty-four hours, each one containing only a little blood and products of tissue destruction, causing an almost constant rectal burning and distress, and giving them no respite day and night. Furthermore, when bleeding is due to some benign lesion there are either no subjective abdominal disturbances, or if present they are very mild; on the other hand, in malignant conditions cramp-like pains in the abdomen are regular, well-marked, and progressive in character.

Loss of Weight.—Contrary to general belief, there is but little direct connection between loss of weight and loss of blood; there is, however, a definite relation between loss of weight and the *cause* of the bleeding. Patients may continue to lose blood from hemorrhoids day in and day out without any appreciable diminution in weight; at any rate, one never sees that decided loss in such conditions which is regularly encountered in malignancy. When it is present, we are justified in suspecting concomitant malignant disease. There is often large loss of weight in chronic diarrhea from whatever cause, with or without any bleeding, on account of the enormous loss of water from the tissues, and the exhausting effect on the patient's nervous system. To summarize then, we almost always meet with great loss of weight in carcinoma, multiple polyposis, and chronic enteroproctitis or coloproctitis, even with little bleeding, but small loss of weight in piles, polyps, and non-malignant tumors, even with considerable bleeding.

Having considered these various factors as they relate to the history of the patient, and given them the weight to which they are entitled, our next concern is to gather what information we can about the bleeding itself. Our chief interest centers about the length of time the patient has been bleeding, the character of the blood lost, whether liquid and

red, or clotted and dark, pure or mixed with pus, mucus, or pieces of tissue, the quantity lost, and its relation to the function of the bowel.

The length of time it has been going on is important as tending in a measure to exclude malignant disease; obviously if the patient has been losing blood for several years it would be natural to assume that the trouble which is causing it is benign. It must not be forgotten, however, that malignant tumors sometimes become engrafted on benign lesions, and what was originally an innocent trouble may in time be transformed into a formidable disease. The writer recently saw an adenocarcinoma started in the tissues surrounding a fistulous tract which had existed for several years before showing signs of degeneration.

The character of the blood expelled is not as important as was formerly taught; merely because one loses blood from the rectum is no proof that the source of it is in that organ. It may come from any part of the intestinal tract, and its color is by no means infallible evidence of its origin, despite the rule which is often accepted, that if the blood is dark it comes from high up, whereas if it is red the lesion which causes it is low down. Blood coming from high up is indeed dark, clotted, and otherwise altered, but only if retained in the bowel long enough; if it should chance to be expelled before these changes have had time to develop it will be bright red. Conversely, blood whose source is low down may be retained in the rectal ampulla long enough to become dark, and possess all the characters of blood coming from high up. We may even sometimes have both liquid and clotted blood from the same lesion, at the same time, whether situated high or low, thus tending further to confuse the issue; hence we cannot draw any positive conclusions from this circumstance until the findings have been confirmed by more reliable data.

The quantity of blood lost depends in a great measure upon the size of the lesion, its character, and the extent of the destructive process. For example, bleeding from a fissure is usually slight, because we are dealing with a superficial lesion, in a locality where there are no large blood-vessels, which, while it tends to chronicity, will not affect the deeper tissues. On the other hand, carcinoma is progressive, erodes blood-vessels, and generally destroys the neighboring structures. Multiple polyposis, ulcerative coloproctitis, amebic dysentery, and diseases of similar character, show extensive areas of involvement, and the pathological process inclines rather to deep destruction than to spontaneous recovery; hence bleeding from such sources is naturally more severe, and the expelled material moreover contains an abundance of mucus, pus, and pieces of tissue, in contradistinction to such innocent causes as hemorrhoids, polyps, procidentia, cryptitis, etc., in which the blood will be found to be unmixed, and show no products of destruction. It may be accepted then, in a general way, that mixed blood points toward serious conditions, though the converse of the proposition does not invariably hold true, for unmixed blood does not necessarily predicate benign lesions.

When there is any pathological condition of the bowel which has a tendency to bleed, any increase in the intraabdominal pressure, due to straining, vom-

iting, or defecation, may initiate it; however, the sudden appearance of a large hemorrhage, without any previous history of rectal disturbance, and independent of any bowel movement, is quite characteristic of some cases of carcinoma of the rectum. In two out of eight of the cases on our records the patients were unaware of any serious trouble with the bowel until the occurrence of the bleeding. One occasionally obtains a history of a similar onset in hemorrhoids or polyp, but close questioning will nearly always reveal a distinct interval of rectal symptoms preceding the hemorrhage.

Perverted function of the bowel and any coexisting bleeding have a definite relation to each other. When there is persistent constipation, the force and straining required to expel the intestinal contents are liable to cause injury to the mucous membrane, aside from any medical or mechanical means used to secure an evacuation; in an impaction the same factors operate with the further addition of a possible necrosis due to pressure of the hard, dry fecal masses on a delicate mucous membrane. When the stools are abnormally frequent they are likely to contain blood from the lesion which causes the diarrhea, if not from the straining and tenesmus set up by the discharges.

These are the roads by which the physician proceeds to uncover the causes of bleeding from the rectum. Inductive reasoning is valuable in so far as it points to the direction in which he must search, but beyond this he must stand or fall by the skill and thoroughness of his examination. Laboratory methods and the x-ray are useful, and in some cases indispensable, but they will always remain in the domain of the trained specialist, whose number will naturally be limited. But every medical man may with little trouble acquire familiarity with the appearance and character of the normal rectum and colon, and the changes which occur in it in disease, and thus discharge a duty which he owes to himself, no less than to his patient.

GONORRHEA AS A CONSTITUTIONAL DISEASE.

BY BURTON PETER THOM, M.D.,
NEW YORK.

GONORRHEA is generally considered, and in the majority of instances acts as, a purely local disease. It is well that this is so, for if grave constitutional symptoms were the rule rather than the exception, it would be, considering its widespread incidence, one of the most destructive diseases that afflict mankind. Yet constitutional symptoms complicating a local urethritis are perhaps more frequent than is usually supposed; but as such they often pass unrecognized, or, rather, are diagnosed as due to some other cause.

Since the evolvement of the gonorrheal complement fixation test we know that the local focus of the disease is accompanied with a constitutional ef-

fect. Clinical observation confirms this in many ways. The constitutional dyscrasia thus produced it is my purpose here to discuss in its various complexities.

The conditions under which the infection becomes generalized are not well understood; nor do we know the frequency with which it occurs, except in gonorrheal rheumatism, which averages about ten per cent. The subject is one which requires much more attention than it has hitherto received. The gonococcus possesses such a wide biological variation and the blood serum of different individuals varies within such a wide range of susceptibility to its influence that it is impossible to state with any degree of accuracy how frequently the infection becomes generalized. Theoretically it would seem to be of very frequent occurrence for the organisms to enter the blood stream; but it must be with almost equal frequency that they are destroyed before they can do any appreciable harm. The constitutional reactions therefore must take place only as the result of a particularly virulent strain of gonococci or where the patient's blood serum is of low bactericidal resistance. Formerly it was believed that systemic infection could occur only by way of the posterior urethra; but now we know that any mucous surface can be attacked by the gonococci, and from thence they pass into the general circulation and give rise to a gonorrheal septicemia. It may therefore be reasonable to suppose that the presence of gonococci in the blood may not cause a sepsis until after a metastasis has taken place. This combination of sepsis with metastasis may be properly termed septicopyemia—which in fact it is.

This brings us to the consideration of gonotoxemia, of which our knowledge is very slight. At present it is impossible to state whether we have to do with an endotoxic poisoning or an ordinary form of toxicosis. It may be said, however, that the consensus of opinion leans toward the former. Experimental toxins (killed cultures) when injected into the body give rise to the same phenomena met with in acute toxicosis generally. These are headache, fever, joint pains, nausea, and vomiting.

As long ago as 1865, Pidoux claimed that in some patients with gonorrhea a general reaction to the disease took place. This was manifest by pallor, dullness of the eyes, relaxed features, loss of flesh, and a peculiar color of the skin. In 1891, Tonis observed that patients with gonorrhea showed a general enfeeblement with pallor. He expressed the opinion that the disease caused a vitiation of the blood as the result of some virulent principle. Aside from those just mentioned various other observers have noted that many cases of gonorrhea are complicated with a slight pyrexia, which some have stated to be of the remittent type and accompanied with enlargement of the spleen. Von Zeissl has called attention to these symptoms as occurring in some patients with gonorrhea.

In 1893, Souflet published a thesis entitled "Gonorrhea a General Disease." Up to that time the gonococcus had not been discovered in the blood, but in the following year Hewes succeeded in making blood cultures. In 1900, Balzer emphasized the fact that it was the gonococcus and not the toxins which was the cause of a constitutional malady. In 1906, Faure-Beaulieu collected notes of thirty-four

cases of gonorrhea in which the gonococci were found in the blood; in three of these a true septicemia existed. Thus for the first time gonorrheal septicopyemia was recognized as a true clinical entity.

It has long been known to dermatologists that skin eruptions are frequent concomitants of gonorrhea. Some of these have been and still are confused with the eruption sometimes caused by copaiba and less frequently by oil of sandalwood. But it is now known that a wide variety of skin eruptions can be caused by the disease.

Among these are herpes facialis, which may be explained by the presence of fever; purpuric rashes and petechiæ, erythema multiforme and even erythema nodosum, papulovesicular eruptions, as well as those of the scarlatiniform type, and a simulation of the "rose spots" of typhoid fever has been observed. According to McDonagh, the most distinctive rash, which he ascribes to a gonotoxic origin, is the so-called "keratoderma blennorrhagica," which he claims is always accompanied with a balanitis. The lesions appear first as vesicles which rapidly become pustular and then the wall of the pustule becomes keratinized. There may be only a single lesion or there may be several, which later may coalesce. The dorsum of the big toe seems to be the point of selection although they may appear anywhere on the body. When the horny process is removed, there is no ulceration beneath, simply denuded epithelium. This condition is very rare. In a somewhat extensive experience I cannot recall ever having seen a case.

The nature of these outbreaks is obscure. They may be septic, febrile, toxic, reflex, or perhaps trophic. It is possible that some may be due to minute emboli blocking the cutaneous capillaries.

While the skin is often attacked, the central nervous system is practically exempt, although a few cases of meningitis and transverse myelitis have been recorded. This is passing strange when we consider the morphological resemblance between the gonococcus and the meningococcus. Peripheral neuritis is occasionally met with but polyneuritis is very rare.

By reason of the constitutional dyscrasia thus developing in the course of gonorrhea it is but natural to expect that many of these patients become anemic. This anemia may be pronounced; so much so that the red cells have been known to be reduced to less than a million in number. On the other hand, the red cells have been enormously increased. This increase is only relative, however, being caused by the concentration of the blood due to the profuse sweats accompanying the sepsis present in these cases. The percentage of hemoglobin falls with the cell count and may reach as low as twenty per cent. As would be inferred, the leucocyte count is increased, chiefly in the polymorphonuclear and large mononuclear cells.

The anorexia that is not infrequently present in acute gonorrhea is not caused, as is usually supposed, by the ingestion of nauseating drugs such as copaiba, santal oil, pichi, etc., but by the septic process acting in the patient's body. The digestive disturbances may become severe, vomiting and diarrhea being present to such a degree as to cause prostration. There may also be enlargement and

tenderness of the liver with more or less jaundice, all of which suggests the septic nature of the condition. These patients sometimes have an angina with functional murmurs of considerable intensity, with a rapid and compressible pulse.

We will now consider the intense forms of generalized gonorrhea, usually fulminant in character and often attended with a fatal result—gonorrheal septicemia and its variant, gonorrheal endocarditis. Gonorrheal septicemia may pursue one of several courses, depending largely upon the metastatic processes which take place. There is a pure blood infection which has a mortality of fifty per cent. and which cannot be distinguished clinically from septicemia of streptococcal origin. This form may also resemble a meningococcal infection so closely that it can be distinguished only by the agglutination test which is positive in meningococcal sepsis either to autoserum or to the curative sera of Flexner or of Dopter. In this form of gonococcal infection it is to be noted that periartritic symptoms may be present. I mention them in order to emphasize the fact that they must not be confused with gonorrheal arthritis. Pleurisy and bronchopneumonia may also develop in these cases, but as a rule are rarely encountered.

It is important to differentiate gonorrheal septicemia from conditions in which there is a clinical resemblance. These are typhoid fever, especially of the ambulatory type, malaria, and anemia. The intensity of the infection may also vary from the hyperacute or fulminant form to the acute, subacute, and benign. When the disease is fulminant, death may occur very quickly from purulent peritonitis—seen mostly in women—or from malignant endocarditis. A clinical diagnosis from the conditions just named is often impossible except that the presence of a urethral discharge is strong presumptive evidence. Blood culture is our principal resource. Absence of the Widal reaction and of the plasmodia of Laveran are of value in exclusive diagnosis. Acute articular rheumatism may be eliminated by the failure of the salicylates as a therapeutic measure.

A symptom complex that not infrequently terminates the septic condition is endocarditis. It may be rapidly fatal. It not infrequently happens that the septicemia and the endocarditis are combined from the onset. In gonorrheal endocarditis the left heart is almost always affected, especially the aortic orifice. The symptoms are typical—prostration, fever, sweats, rapid and irregular pulse, murmurs, dyspnea, and cardiac erythmism. In the malignant type, ulceration and proliferative vegetations occur on the valves, which not infrequently are broken off and carried away by the circulation to form emboli. The clinical picture just described is not always present. In very many instances the endocardial inflammation comes on insidiously with cachexia and signs of cardiac irregularity. These cases are as a rule ambulatory and mistakes in diagnosis often occur.

From a study of the literature, which is becoming more and more extensive, it is evident that the local urethral disease not infrequently becomes general with symptoms which may assume a character similar to other generalized infections. While it must be borne in mind that comparatively few cases of

gonorrhea react in the manner just described, yet it is my opinion, based on considerable experience, that gonorrhea reacts constitutionally much more frequently than is generally supposed. Indeed, I have come to believe that almost every acute gonorrhea is attended with more or less constitutional disturbance—the “first” gonorrhea especially. The fact that in the vast majority of instances the disturbance is only slight is why it is so often overlooked. I will make an exception in so far as gonorrheal rheumatism is concerned, which has not been dwelt on here. My reason for not doing so is that the subject is so full that it would be impossible to do it justice in the limited space at my command, and I have therefore reserved it for a future communication.

The conclusion to be reached in this brief study of one of the phases of gonorrhea is that it is the part of wisdom to watch carefully the development of any untoward febrile or cachetic symptoms occurring in the course of the disease, let it be acute or chronic. It is quite possible that they may be caused by the condition which was looked upon as purely local.

1632 AVENUE A.

Medicolegal Notes.

Privileged Communications—Waiver—Different Witnesses and Different Transactions.—In an action for an injury caused by a fall on ice on the defendant city's sidewalk the injury was alleged to have been sustained about the 26th of February, 1914. The plaintiff testified concerning it, in effect, that it injured her left leg and left hip and made her arm sore; that it caused a numb feeling all through the lower part of the bowels and about the ribs; that it made her feel sick; that she had hard work to get home, and was sick and weak after she reached home, and remained in that condition for several days. A medical witness testified for her, in effect, that his books showed he first treated the plaintiff on February 26th and continued to treat her for a day or two; that no other doctor was with him; that he discovered a tenderness in the region of the pelvis which could be ascertained only by feeling; that the muscles were on tension and comparatively hard; that he found some swelling and a tenderness between the navel and the pelvic bone, and some fever.

Did this testimony open the door to letting a doctor, whom the plaintiff did not call as a witness, disclose what he obtained professionally during the period covered by the testimony adduced for the plaintiff to the extent of telling any and all things he then found the matter with her, and all differences in ailment then existing? In answering this question, the Iowa Supreme Court is of opinion that the policy of the statute may not be left out of consideration. That statute should have a liberal construction because its purpose is to make it possible for every person to consult fully and fairly with a physician or submit himself to his examination without anticipation or fear that the confidence reposed may be broken in upon by a subsequent examination of the physician as a witness. There is no punishment provided for the physician who reveals what has been confided in him. About all, then, that the statute could have aimed to do was to prevent revealing on the witness stand. It must have been understood by the Legislature that those who made confidential revelations to physicians might enter into and produce testimony in litigation, wherein it would be very material, either as impeachment or otherwise, to have the physician disclose what he had been told, and it must have intended, therefore, that the occurrence of these conditions should not operate to waive the privilege. It has therefore been held that such testimony is not made admissible because it will impeach, nor because it will operate to defeat falsehood. And that the naked fact that the plaintiff makes a witness

of one of her doctors does not give consent that the defendant may make use of any or all other of the plaintiff's doctors, and have them testify on the same general subject to which the plaintiff's witness spoke. The plaintiff may be willing to waive the objection as to a witness in whom he reposes special confidence, yet insist on it as to another. This doctrine, citing prior cases, the Iowa court followed, adding that it follows as a corollary that a waiver of the privilege as to one transaction will not operate to waive it as to other and independent transactions.—*Jacobs v. City of Cedar Rapids*, Iowa Supreme Court, 164 N. W. 891.

Opinions of Physicians in Evidence.—Physicians in testifying concerning examinations of the plaintiff in an action for alleged injuries resulting from a fall in the defendant's street car and their opinions derived therefrom were permitted to say that they believed she was shamming. This was claimed by the defendant to have been erroneous as an invasion of the province of the jury, who alone were to determine whether or not the plaintiff was injured. It was held proper to receive evidence of the condition of the plaintiff when so examined, and the opinion of these witnesses as to whether or not she was then suffering from any injury. But whether she was honest or dishonest, sincere or shamming in respect to her claims of pain or injury was a matter about which the jury might have drawn their own conclusions from the facts given by the physicians without their opinions. A search for authorities disclosed, however, that similar evidence has in some cases been admitted by the courts of New York, Illinois, Michigan and Texas; and it was held that while such evidence should be viewed with strictness and caution, its reception in this case was not error.—*Hopson v. Union Traction Co.*, Kansas Supreme Court, 167 Pac. 1059.

Practising Without a License.—In an action to recover the penalty provided for by the Illinois statute for practicing medicine without a license, the following evidence was held sufficient to sustain a judgment against the defendant. The proof showed that the defendant treated one person for stomach trouble and nerves for a long time by rubbing her with her hands, and told her to eat fruit and to take long breaths many times daily. She also told her she was getting along all right and collected \$1 per treatment. One witness testified that the defendant treated her for nervousness for three years by rubbing her all over; that before starting the treatment the defendant asked witness questions about her trouble, “Just about like a regular doctor would,” and told her what the trouble was; that it was nervousness, and that witness paid her \$1.40 per treatment. Another witness testified that the defendant treated her by rubbing; that she had been ailing and had been to a doctor about it; that the defendant told witness her trouble was constipation, and that she paid her \$1.50 per treatment. Another witness testified that the defendant treated her for nervousness three times a week for five months and occasionally for three months more by rubbing; that she told her she could cure her; that she would guarantee that witness would get well; that witness went to her as an osteopath and told her so, and the defendant took her as her patient as an osteopath; that she called the treatments osteopathic, said she was an osteopath, and gave directions as to what witness should eat; that the defendant charged her \$1.40 per treatment.—*People v. Brown*, 202 Ill. App. 530.

Sunstroke Held an Accident.—The Minnesota Supreme Court holds that sunstroke is a “personal injury caused by accident” within the meaning of the Workmen's Compensation Act.—*State v. District Court (Minn.)*, 164 N. W. 916.

Harrison Law—Prescribing Opium.—The federal district court for the District of Montana holds that, the Harrison Law requiring nothing of physicians issuing prescriptions for opium, save that the physicians be registered, and the prescriptions be signed by the physicians and dated, and not limiting the amount which may be prescribed, an indictment merely charging the defendant physician with giving a prescription for and so dispensing pounds of opium charges no offense, “dispense,” as used in the act, relating to the actual delivery of the drug.—*United States v. Reynolds*, 244 Fed. 991.

Military Medicine.

RAT-BITE FEVER IN THE TRENCHES.

IF Dante were alive now with his masterpiece unwritten he would undoubtedly make the first cycle of his *Inferno* the trenches. At least that is the impression gained from a perusal of the pathological side of life there. Trench-fever, trench-shin, trench-foot, pediculi, nephritis, and a host of other evils are described in the literature seen in foreign medical journals nowadays.

Then, too, besides the diseases peculiar to; or enhanced by, trench-life other diseases are appearing from time to time which have their origin in the unsanitary conditions which prevail there in spite of all efforts to the contrary. To be sure, we live in an age where we do not fear that our troops will be decimated by the plague, smallpox, or hospital gangrene, but at the same time the unique environment of the fighting man to-day—between walls of damp earth, his feet in refuse, mud, and icy water, often overrun by fleas and lice, harassed by rats—is responsible for the appearance of diseases which we had almost forgotten in civilized communities nowadays.

For example, rat-bite fever, which is common enough in certain countries and climates, is not likely to be very familiar to the average American doctor. It has, however, made its appearance in the trenches and we may expect before long to hear of cases among our soldiers. Therefore we notice with interest that several Japanese writers have discovered the cause in a spirochete which they have been able to demonstrate in the blood, skin, and lymph-glands of seven out of ten cases which they have examined.

These spirochetes are described as being thick and short (about two to five micra.) and have flagella at both ends, which increase their length to from six to ten micra. The smaller ones are formed in the blood and the larger ones in the tissues. They stain easily with Giemsa and with ordinary aniline dyes. Their movements are perceptibly more rapid than those of any other known spirochetes, this forming a distinguishing characteristic until they are stained, when the movements slow down greatly. These spirochetes are present in the swollen local skin lesions; in seven cases out of eight they disappear on recovery, only to reappear on relapse. This organism appears to be present in about 3 per cent. of all ordinary rats, and has never been found in healthy guinea-pigs or mice. However, it may be transmitted to them by having them bitten by an infected rat.

The clinical symptoms of rat-bite fever are inflammation of the bitten parts, paroxysms of fever of the relapsing type, swelling of the lymph-glands, and eruption of the skin, all occurring after an incubation period of one to three weeks or longer. The writers believe that other causes may exist for these symptoms than the spirochetes described above, but think that they are the cause of the form most common in Japan.

Ordinarily, of course, the investigation of such a disease as rat-bite fever would have for the average practitioner but an academic interest. But in these parlous times, when no one knows unless he has donned the lean and slippered pantaloons—and

not always then—at what minute he will be called to the front, it behooves us all to be conversant with the peculiar perils besetting our men. The next step is to find a cure for the disease. Granting that the *Spirocheta morsus muris* is the cause, or the chief cause, a spirocheticide is next in order. We know that it is markedly affected by salvarsan. Whether or not this preparation of arsenic or some other one will prove to be the ultimately selected remedial agent time alone will tell. In the meantime we are indebted to our Nipponese allies for the pertinent discoveries cited above.

Medical Problems on the Italian Front.—In a paper read before the Section of Experimental Medicine of the American Association for the Advancement of Science at Pittsburgh, on December 31, Dr. Victor G. Heiser gave an interesting presentation dealing with military problems on the Italian front. He said that it seemed to be a peculiarity of persons who were sent abroad on missions to various countries to return ardent partisans of the country they set out to visit, in spite of accidents and difficulties which might occur. People who went to Russia on a mission were enthusiastic for the good ideas which they were convinced would grow out of Russian mistakes. Those who, like himself, went to Italy refused to believe in her ultimate overthrow. He thought it better to interest his audience in a few salient facts which he had observed during his mission, and which would speak for themselves. The Italians were extraordinarily efficient in their medical organization. Italy when she went to war was worse off than any other belligerent country. She had no x-ray apparatus that was not manufactured entirely in Germany; no ammunition and no automobiles that had not come from there. Since the outbreak of the war she had manufactured all the automobiles she had been using, and the fact that she had as many motors for transportation as any of the belligerents would show the immensity of this accomplishment. Not only this, but a sufficient number of cars were made to allow of export to France and to America. Some motor factories also made airplanes, the quality of which was well known, by the Caproni standards. Not a single battle-plane had been made in America for Italian use. It was stated that the British Government had offered every facility to the United States to manufacture battleplanes, but the offer had not been taken up. Italy had manufactured them by the dozen.

Italy had had to face very serious sanitary problems since the beginning of the war. The Austrian prisoners had carried cholera into the Italian camps and the medical service had to vaccinate the entire army against cholera. The laboratory staff had to make examination of the stools of all the soldiers and prisoners who came from infected regions. To convey an idea of the immensity of this task to Americans, who imagine that nobody can exceed them in large undertakings, it was stated as a fact that an average of 3,000 stools a day were examined. In regard to the question of quarantine, it was considered an immense undertaking in this country when the Surgeon General instituted a quarantine station capable of dealing with 2,000 inmates. That was a mere bagatelle to the enormous

numbers that the Italians had to deal with. All the troops returning from Salonica—French, British, etc.—came through southern Italy, on account of submarine dangers by sea. The Italian quarantine for the British had a capacity for 20,000 persons, for the French 40,000. Examinations for malarial plasmodia were made in the blood of all these quarantined. To return more specifically to the Italian front, the medical men had shown admirable resourcefulness. The general idea was that the Italians did not get very far, but they had completed hospitals with a capacity of one million beds. America had been 100 years in building hospital accommodation for 30,000 beds, while the Italians had built a much larger number in six months. The construction of these hospitals was exceptionally good and workmanlike. There were no luxuries, but all the essentials were there. Practically no tents were used, although the British and French armies were still relying largely on tents. The construction of Italian hospital buildings cost less than that of tents and was very strong. A unit was a building 6 feet by 12, and 14 feet high, constructed of fireproof tiles. It was cool in summer, warm in winter, sanitary and efficacious, and if needed could be built in sizes to accommodate any number of patients. In some medical centers there were 40,000 beds. The same number of buildings in France were a heterogeneous collection, but in Italy even a neat type of architecture was carried out. Hospitals were dedicated to special injuries, such as fractures of the lower extremity, lung wounds, jaw wounds, etc., where special care could be given to the defect.

The problem of "mobile hospitals" had been worked out to perfection. By means of a 150-bed hospital, carried on five motor trucks, it was possible for the surgeon to travel 75 miles from the point of the last operation in 16 hours. He took his whole staff of assistants and nurses with him and was ready to operate again. These hospitals were maintained at one-third of the cost expended by other belligerents. The Carrel treatment and all other modern techniques were employed. In regard to prosthetic treatments, the Italians were among the most adroit in reconstruction. Much had been read of the Roehampton Hospital in England, but the Marguerita Hospital in Rome far outclassed it in ingenious appliances. In Bologna a man was seen who had lost both hands, but was still able to eat with knife, fork, and spoon.

The cooking problem was dealt with as efficiently as the work of hospitalization. The Italian soldiers received hot food in the front line trenches, handled by means of fireless cookers; cooked at 8 A. M. and served at 11 A. M. The management of the work was perfectly marvelous.

These unfortunate people had recently suffered terrible reverses, but it could be said for them that they differed from the rest of the Allies in one respect, particularly—the English and the Americans were accustomed to boast of what they were going to do, and then go and do it; the Italian, on the other hand, went and did the thing, and then, perhaps, talked about it later.

From Verdun to Mannheim.—Dr. Simonin, a French medical inspector, taken prisoner at Verdun after having been wounded, and soon ex-

changed, has published an account of his sojourn in Mannheim, which is reviewed in the *Bulletin of Le Progrès Médical* for November 10. The battle in which he was injured occurred in August, 1914, so that the title of his book is somewhat misleading, the suggestion being the Verdun of 1916. As a wounded prisoner he would have been shot had he not called out to the German subaltern to "get special instructions" because he was not only a physician but a professor in the Military Academy at Paris. The officer instantly saluted and withdrew, and Simonin had managed to escape the infamous "Gommery massacre" as it will be known in history. Of 300 wounded French prisoners, all but 75 or 80 were killed in cold blood while the town was being fired. One doctor whom three fusillades had failed to kill was left to die in a burning house. It was thought that the massacre was over, but on the following day Dr. Maxence and three orderlies were assassinated. The former told the Prussian that he had killed a physician and received the reply "c'est la guerre." The murders ceased as soon as an upper staff physician, Zedler, had arrived and established a field hospital, which suggests that the alleged motive for the massacre was the total lack of hospital facilities. Zedler proved to be a "good boche," and as if to make amends for the acts of his countrymen treated his French colleague with the greatest courtesy. When Simonin was transferred to a base hospital the physician in charge, Dr. Prizel, continued these courtesies. By reason of the presence of the Frenchman they even refrained from singing patriotic songs on the anniversary of Sedan.

At the next transfer point things were not so pleasant. The hospital had been stripped of supplies and drugs and the physician in charge was not amiable. He was two days on the road and as provisions were scarce was asked to pay something. At Mannheim he was interned in a deaconesses' home, which he likened to a gilded cage. The deaconesses treated him with extreme consideration and the medical man in charge, Dr. Seubert, was unostentatiously kind. By steps which are not explained the prisoner was soon in Switzerland on his way home. The scrupulous observation of the Geneva Convention in some quarters with its total disregard in others was a source of mystery to the prisoner. In regard to the massacre the lack of insignia of their office on the uniforms of French medical officers and stretcher men could perhaps have been held responsible for their murders. The book has a preface by Abbé Wetterlé, who is noted for his activities in "getting the goods" on the German Army in connection with atrocities of all kinds.

Preparing to Care for War Cripples.—The Red Cross Institute for Disabled Men, which has its headquarters at 311 Fourth Avenue, New York, has issued an appeal to employers for suggestions as to the places to which cripples may be assigned. This information is for the use of the institute's employment bureau. The statement issued by the Institute declares that there have been 5,200 men disabled on the Italian front up to July, 1916,

and describes how Italy is caring for these men and reeducating them so that they will be self-supporting. Schools for the reeducation of cripples have been opened in seven principal Italian cities. In carrying out this campaign the institute announces that it does not want to place men on a charity basis or give them work for which they are not qualified. By obtaining information as to fields open for cripples reeducation can be more wisely directed.

Kings County Base Hospital to Mobilize.—The Kings County Base Hospital Unit 37 received orders to mobilize at the Twenty-third Regiment Armory, Brooklyn, on January 4. The unit was organized by Dr. Edwin H. Fiske, who is in command of the surgical staff. Colonel B. H. Dutcher of the Regular Army Medical Corps will command the unit. It is understood that the unit will undergo intensive training for a short time before being sent abroad.

Teuton Airmen Murder Hospital Inmates.—A report received at the War Office states that on the night of January 1 German airmen dropped bombs on Castelfranco, Veneto, striking two hospitals. Eighteen patients were killed.

Huns Torpedo Another Hospital Ship.—The British hospital ship *Rewa* was torpedoed in the British Channel while on her way from Gibraltar at midnight of January 4-5. All the lights and markings showing that she was a hospital ship were visible. Three of the crew were lost, but the wounded were all transferred to patrol ships before the *Rewa* sank.

Poets' Committee Reaches Goal.—This committee announces that it has succeeded in obtaining funds for the 100 ambulances for the Italian front. This was the main purpose of the committee, though as a by-product it has established five barrack hospitals and thirty-two tent hospitals at the request of the Italian authorities.

Offer of Sanatorium Declined.—The authorities at Washington have declined the offer of the use of the Otisville Tuberculosis Sanatorium for a medical depot recently made by the municipal authorities of New York. In the offer to the Government was a clause to permit its revocation "on thirty days' notice in writing to the Secretary of War."

Spartanburg Camp Has Low Death Rate.—According to a report sent by Major-General O'Ryan to Governor Whitman, there have been only nine deaths from disease among the 31,000 New York troops at Camp Wadsworth since the men arrived there last August. During this time there have been five deaths from railroad and automobile accidents.

New Red Cross Hospital Opened in France.—Another of the chain of hospitals which the American Red Cross is establishing in France for the care of the civil population was opened in Lyons on December 3, in the presence of the representatives of the American Red Cross, the Rockefeller Foundation, and the French authorities. The Ste. Eugénie Hospital at Lyons has been lent to the Red Cross by the hospital board of Lyons, which supplies the building with heat, light, water, and sanitation, without cost to the Red Cross. The food, linen, and disinfectants are supplied at cost,

and the Red Cross provides the doctors, nurses, and hospital supplies. This hospital will care for refugees suffering from tuberculosis.

False Teeth More Deadly Than Battle.—An instance of what chance may do is afforded by the case of Albert Crome, an English soldier, who enlisted two years ago and served fifteen months in France, where he participated in a continuous series of desperate fights. Becoming ill he was sent to recuperate. On his first night home he swallowed his false teeth, and died.

Deaths in Pershing's Army.—In a cablegram, under date of December 31, General Pershing reported to Washington that there had been fifteen deaths in his army. These mortalities were all due to disease except two. Pneumonia caused the largest number, with tuberculosis a close second.

Many Thousands of Nurses Wanted.—The United States Army is in need of nurses for immediate assignment to duty and for reserve. It is confronted by the task of increasing the enrollment nearly 1,000 per cent. to procure 37,500 nurses who will be needed for an army of 1,500,000. The present strength of the Army Nurse Corps is but 4,000. The need for nurses in army hospitals in this country and for duty overseas is urgent, but the enrollment has not met the demands by a large number. Hospitals of National Guard and National Army camps still need 290 nurses to bring the quotas up to the necessary minimum of 65 nurses to each hospital. Since the urgent need for more nurses was announced in December, over 2,000 requests for application blanks have been received, 400 nurses have applied for enrollment and many have been accepted. About 650 nurses have been obtained through the Red Cross during the same period. The call to duty is made to every one of the 80,000 registered and 200,000 other graduate and practical nurses in the United States. That the enrollment has not been larger is due, it is believed, to the lack of realization by American nurses of the immediate need of their services. The Army Nurse Corps impresses the profession in this country with the urgency of that need. Besides the number needed for immediate assignment to duty, there must be a reserve for call when American casualties increase. As soon as the immediate needs of cantonment hospitals have been cared for, a reserve of 100 nurses will be organized for emergency service in the United States. The Lakewood Hotel at Lakewood, N. J., has been leased by the government for use as a general hospital and provisions will be made for housing nurses there. Because of the immediate need of nurses and to encourage enrollments, a number of the requirements heretofore imposed have been waived. Requests for information, applications, and enrollment should be made to the Surgeon-General, U. S. Army—attention of Superintendent, Army Nurse Corps, Mills Building, Washington, D. C., or to the Director, American Red Cross Nurse Service, Washington, D. C.

Dr. Andrew MacPhail Knighted.—Among the New Year honors was the conferring of knighthood upon Dr. Andrew MacPhail, professor of the history of medicine at McGill University, Montreal. Dr. MacPhail is at present a captain in the Canadian Army Medical Corps.

CONGENITAL HEMIATROPHY OF THE DIAPHRAGM.

THIS very rare congenital defect was first described by J. L. Petit in 1774 and afterwards confused with diaphragmatic hernia until 1829, when B  clard and Cruveilhier defined it as a diaphragmatic eventration. In 1894 J. Tennant recorded a case of partial atrophy of the diaphragm. He found at autopsy a laxity of the two posterior thirds of the left side of the diaphragm which had been pushed up as high as the second intercostal space. The diaphragm, which was otherwise normal, was lax and flabby at this point, the muscular fibers being very thin and scattered. Tennant looked upon the case as congenital in origin.

With the advent of the x-rays more cases were recognized. In 1900 Hirsch diagnosed a diaphragmatic hernia in a man named Schneider, who afterwards traveled from clinic to clinic in Germany and whose case gave rise to much prolonged polemic. Hilderbrand and Hess pointed out that the linear shadow in the form of a dome that Hirsch looked upon as the gastric cupola followed the respiratory movements in the same direction as the right costodiaphragmatic sinus; the shadow, therefore, in their opinion, corresponded to a thin diaphragm since it offered no solution of continuity, and for this reason they adopted the term of diaphragmatic eventration given to the condition sixty years previously by the French observers. Later on, Lotze upheld Hirsch's view of the case, while Hess replied that the famous Schneider was the possessor of an eventration, because electrization of the phrenic nerve caused a marked contraction of the much discussed convex shadow. Autopsy at length proved that Hildebrand and Hess were correct.

Quite as interesting as the case of Schneider was that of a patient studied by Widenmann and afterwards by Glaser. The diagnosis of diaphragmatic hernia was made because the patient had upon several occasions offered phenomena of gastrointestinal occlusion, but at operation K  rte simply found the diaphragm raised to the level of the left nipple. Autopsy showed that the left side of the diaphragm was thin and pale in color. The muscle fibers were the seat of a marked fatty de-

generation. The same anatomical condition was found by Doering in a man 60 years of age who died from cardiac collapse and who had never presented abdominal symptoms during life.

Of late such cases have been more frequently reported, the latest being by Betchov (*Revue m  dicale de la Suisse romande*, July, 1917). From examination of his own case and those more recently recorded, Betchov believes that they are instances of congenital hemiatrophy of the diaphragm, two cases in newly born children having been observed by Glaser. In the cases where the diaphragm was examined there was fatty degeneration of the few muscle fibers which still remained embedded in a fibrous tissue, and such changes cannot be attributed to the phrenic nerve.

This congenital defect, which does not appear to be frequently accompanied by other malformations, may be seated in either half of the diaphragm. It is uncommon on the right side and when occurring on the left this half of the diaphragm is forced up into the thoracic cavity while the stomach and other abdominal viscera become lodged in the area occupied by the heart, which in turn is pushed to the right. In these circumstances radioscopy shows that the involved half of the diaphragm is atrophied and offers a limited respiratory movement, while the right costo-diaphragmatic sinus follows an amplified inspiratory movement.

The affection may not cause any subjective disturbance during life, but in some cases it may result in gastric and peritoneal phenomena resembling strangulated hernia, these being probably due to the progressive torsion of the stomach which pivots around the fixed cardia. The infrequency of digestive disturbances is quite remarkable. Clinically, this affection may be mistaken for dextrocardia, either congenital or following a left pleural collection or hydropneumothorax.

TRINITROTOLUENE POISONING.

ACCORDING to an article by Hamilton in the *Journal of Medicine and Surgery* for September, 1917, there were 703 cases of TNT poisoning among munition workers in the United States during 1916, with 13 deaths. While the morbidity and mortality, as shown by these figures, are not very excessive in view of the large number of people now employed in munition factories, still the condition is sufficiently prevalent and important to warrant a much wider medical discussion than it has heretofore received on this side of the water. The probabilities are that during 1917 the incidence of TNT poisoning has been greater owing to the increased production of munitions consequent upon the entrance of America into the war. Aside from the actual number of cases recorded there is reason to believe that a considerable number go unrecognized, or are diagnosed as other diseases. The question then naturally arises as to what constitutes TNT poisoning. In this connection it might be stated that in Great Britain only cases which exhibit evidences of toxic

jaundice are reported to the health office. The series of 703 cases recorded in the United States last year include, in addition to the cases of toxic jaundice, those patients who displayed symptoms of toxic gastritis. A symposium on the subject, held before the Royal Society of England in January, 1917, brought out the fact that many munition workers suffer from mild symptoms of poisoning which may incapacitate them for a few days only, but that the severe form of the disease renders them unfit for further duty for a long period, if indeed they do not succumb to the pronounced toxemia.

There has been a great deal of discussion abroad anent the portal of entry of the poison. It is now conceded, however, that the skin and respiratory tract are the principal routes through which it gains access to the system. Which route takes precedence over the other has been the question in dispute. At one stage in the manufacture of the explosive, it occurs in a molten state, when fumes are given off that may be inhaled. The molten mass is poured into the shells and allowed to solidify. After this takes place the charge is planed and trimmed to the correct size and weight; holes are then bored to insert the detonators. These procedures lead to the formation of TNT dust, which settles on the skin or is rubbed into it, where the deleterious ingredients are readily absorbed. Oil on the skin facilitates absorption. It has also been shown that fumes are given off from the powder at temperatures as low as 32° C. (89.6° F.). These fumes are likewise susceptible of inhalation. It is interesting to note that cases of poisoning are most prevalent in the hot summer months. The weight of evidence so far adduced appears to be in favor of the cutaneous route over the respiratory as the chief portal of entry of the materies morbi. The gastrointestinal tract is said to play a role in absorption, but this channel is considered to be of secondary importance by the majority of authorities.

The early symptoms of TNT poisoning are often indefinite. Weakness, headache, unexplained cough, cramplike pains coming on suddenly in the legs, anorexia, nausea, and occasionally morning vomiting, are among the commonest met with. In severe cases the attack is ushered in by pain in the abdomen, jaundice, nervous manifestations, and coma. In some of the cases a progressive anemia of the aplastic type ensues. Dermatitis is relatively common, occurring in the form of a blotchy erythema with edema. Constipation is the rule, diarrhea being rare. The poison seems to have a cumulative action, and may show its toxic effects some time after the worker has left the factory. The largest number of cases develop in workers filling and finishing shells, as in these manipulations they are exposed to the dust and fumes to the maximum degree. The lesions found at post-mortem examinations are those of acute yellow atrophy of the liver, fatty changes in the kidneys and myocardium, petechial hemorrhages in the serous membranes and skin and in the yellow bone marrow. Frequently the blood is

bright cherry red in color and watery in consistency, with very little post-mortem thrombosis.

Treatment is purely symptomatic and chiefly eliminative. "An ounce of prevention is worth a pound of cure" is an adage which applies with particular force in this condition. The preventive measures employed are designed to minimize dust and fumes as far as possible by exhaust devices. Personal hygiene is important, especially attention to the skin and scalp. Gloves should be worn, and the scalp covered by a tightly fitting cap. Plenty of fresh air and good food are in order. Periodic alternation of shifts, so as to reduce the exposure to the poison, and prompt removal when toxic symptoms threaten, are essential.

WAR BREAD.

ALTHOUGH in this country there has been as yet no rationing and only suggestions as to the kind of bread that should be eaten, it is probably merely a question of time before certain rules will be laid down with regard to the consumption of food and to the best means for conserving the same. In Great Britain what is known as war bread has been in use for some months now, and it is interesting and instructive to acquire information regarding its effects on health. The composition of the war bread made in Great Britain differs from that of the ordinary bread manufactured from highly milled flour in that the latter contains only about 70 per cent. of the whole grain, the bran and germ being discarded. The milling regulations of the Food Controller of Great Britain make it compulsory for millers to extract 81 per cent. of the whole wheat grain in the form of flour; thus the inner layers of the bran or pericarp and some of the germ enter the flour. Dr. Robert Hutchison, writing in the *Practitioner* for December, 1917, points out that chemically the British Government regulation flour is undoubtedly superior to the old white flour. It is richer in protein, fat, mineral matters, and vitamins, but slightly poorer in starch. Experiments on the human subject have shown that there is no practical difference between the utilization of energy from "war flour" and the ordinary white flour, provided that the war flour is well milled.

However, the question of bread in Great Britain is still more complicated by the fact that in order to conserve the wheat supplies as much as possible millers have been empowered to add other cereals to the flour up to certain maximum limits. The cereals which have been chiefly employed for this purpose are corn, barley, rice, and oats. Of these, corn has come in for the most criticism, mainly no doubt because it is less familiar as an article of food than the others. Objections are made to corn on the grounds of flavor, which may be dismissed as unworthy of notice in wartime. Another objection which carries some weight is that corn is what is popularly spoken of as heating, that is, it tends to cause skin eruptions of an acneiform or urticarial nature. Hutchison says that the effect is appar-

ently not due to any chemical constituent of corn, and he believes that it is mainly a question of mechanical irritation of the stomach by particles derived from the husk of the grain, and that the skin lesions are produced indirectly through the vasomotor system, much as flushing of the face follows immediately in some people on the taking of alcohol. On the whole, then, Hutchison thinks that there is justification for the conclusion that there is nothing chemically injurious in the flour from which the war bread is made, and that any ill effects from it can be due only to imperfect grinding. Summing up the whole situation, Hutchison is of the opinion that it may be said with confidence that the only possible objection to war bread consists in its physical characteristics, lack of porosity, "doughiness," heaviness, etc., objections which exist to any important degree only in certain localities and in the bread produced by individual bakers, and which in any case can to a large extent be overcome by toasting the bread and by thorough chewing. It follows then that it is only in disorders of the alimentary system that the bread could produce any ill effects. Owing to its nourishing properties, and its chemical purity, it is inconceivable that disease elsewhere could be unfavorably influenced by it. Hutchison believes it to be a delusion that dyspepsia is caused by war bread. The author did not mention two points in which war bread is superior, from the dietetic standpoint, to white flour bread. These are that it does not tend to constipate as does the white-flour bread, and that on account of its consistency it requires more thorough mastication, thus promoting the action of the salivary glands and aiding the organs of digestion.

GENITOGLANDULAR DYSTROPHIES.

OF the various types of dystrophy and arrest of bodily and mental development it may be affirmed that in only a certain percentage is an endocrine factor surely present. Moreover, the majority of cases are not reported before the adult or at least adolescent period. These two facts confront us always when we attempt a close analysis of dystrophies. Any condition which can be termed infantilism cannot, of course, be studied in childhood nor can genital dystrophies be apprehended in advance of puberty whether normal or precocious.

In the notice of a Brazilian article by de Souza and de Castro in the *Revista de la Asociación Médica Argentina* for September, 1917, it is stated that 22 unpublished cases of genitoglandular dystrophy are reported, yet the reviewer does not mention the ages of the subjects. Whether it is proper to term such cases "glandular" in the absence of autopsy finds is a moot point.

By reason of their finds the authors isolate five types of dystrophy. In three of the subjects there was evidence of tumor of the hypophysis, but the exact complication of the glands does not enter into the classification beyond the fact that genital atrophy was constantly present. The arrangement

does not differ materially from that of ordinary classifications, the types comprising infantilism, gerodermia, eunuchoidism, and the adiposogenital and pleuriglandular syndromes. To these may be added the simple or uncomplicated type in which only the genital organs are involved.

The infantile type can be present only in those who have arrived at or passed puberty. The reviewer does not agree with the authors when they state that genital hypoplasia alone is sufficient to cause infantilism.

The senile and eunuchoid types are more or less mixed, and it is in these two forms—although the reviewer does not mention it—that the presence of an endocrine factor is often in doubt. In a series of cases of eunuchoidism recently published by Sterling, that author was very skeptical on this point. On the other hand, Froehlich's disease is always associated with the hypophysis. The pleuriglandular type is largely negative, residual, and comprises all cases which do not sort themselves under the preceding.

FECAL EVIDENCE OF GASTRIC INSUFFICIENCY.

THE stomach has the twofold office of protecting the segments of the gastrointestinal tract which lie beyond it and of preparing the food for further elaboration. Gastric juice is the only digestive fluid which can act upon the connective tissue of animal food and dissociate the vegetable cells with liberation of certain crystals. Whenever the stools show entire muscle fibers with their transverse striation, and fragments of potato or carrot along with crystals of oxalate of lime we may feel assured that there is present a state of gastric insufficiency consisting more especially of a defect in the production of hydrochloric acid. Other evidences of the same state of affairs are seen in a stool content of certain intestinal parasites in large numbers, such as *Ameba coli*, *Trichomonas intestinalis*, *Lamblia intestinalis*, etc. Still other evidences are visible in the color of the feces due to rapid oxidation of the bile pigment occurring upon exposure to air. Hence the stools, yellow on passage, become dark brown on the exposed surfaces, although fluid evacuations often occur. These observations of Goiffon in the *Archives des maladies de l'appareil digestif et de la nutrition*, 1917, No. 5, emphasize the extreme ease with which gastric insufficiency may be recognized with low powers of the microscope, although the treatment test of HCl in all suspicious cases is so readily available that the practitioner may spare himself the burdensome labor of fecal examination in many cases.

SURGICAL TREATMENT OF INTESTINAL STASIS.

THERE is still a good deal of difference of opinion as to the treatment of that condition known as intestinal stasis. Some believe that operative measures should be taken in a very large number of cases; some think that surgical intervention is almost always contraindicated, while others are of the opinion that strict conservatism should be the motto when dealing with intestinal stasis. In the *Annals of Surgery* for October, 1917, Dr. Albert J. Ochsner gives his views on the subject and discrim-

inates with regard to the cases requiring operation as follows: "After eliminating the very large number of patients suffering from intestinal stasis who are primarily neurotics and suffer from intestinal stasis only secondarily, who are practically never benefited by surgical treatment, and the still larger number of cases suffering from intestinal stasis who can be permanently relieved from this condition by exercise, hygiene, dietetic and carefully planned, long continued medical treatment, there still remains a very small class of cases in our experience comprising less than 5 per cent. of all cases suffering from intestinal stasis, which constitute a third and distinct class whose members are not primarily neurotics and who are in so intractable a condition of intestinal stasis that they cannot obtain relief from non-surgical measures." Ochsner is not in favor of the radical measures advocated by Lane and his followers and proposes an operation first described by him in 1916, with an additional step suggested by Dr. William J. Gillette of Toledo, Ohio. The point to which it is desired to draw attention here is that in Ochsner's opinion there are less than 5 per cent. of cases of intestinal stasis which call for operation, and, further, that when such intractable cases are met with, the operation performed should be as conservative as possible.

A GASTRIC TRIANGLE.

IT is somewhat curious, in these days, to learn that anatomists have overlooked, and consequently failed to describe, what is said to be a prominent and conspicuous triangle on the surface of the human body. Dr. George Elliott, who has traced the triangle, and who has described it in the *Dominion Medical Monthly* for December, 1917, terms it the umbilico-mammillary triangle. The base of the triangle is the line between the two mammillæ, its apex the umbilicus, its sides the lines connecting the umbilicus with the right and left mammilla respectively. The stomach can, therefore, be pictured lying behind the left half of the triangle; the fundus taking a sweeping curve up to and just below the apex of the heart; the lesser curvature, curving down to the pylorus, with its concavity to the right, and lying almost wholly in the left half of the triangle, the greater curvature curving to the left downward to or a little below the umbilicus, but running outside the left line.

As the pylorus lies under the liver, the lower border of the latter may practically be located at that point, one-third the height of the triangle up from the apex at the umbilicus. The pancreas may be pictured as lying deeper than the stomach, crossing the apical third of the triangle. Elliott points out that at the present time, in studying the landmarks of the apex of the heart, mitral and tricuspid valves, the cardia, the pylorus, fundus of the gall-bladder, as well as the locations for the incisions for the various operative procedures on the stomach, duodenum, and gall-bladder, the student is apt to become rather perplexed over these surface markings. If, then, all these organs can be grouped in relation to the umbilico-mammillary triangle, which is remarkably distinct, the student will have presented to him a clear clinical picture of the region in which these organs are situated.

News of the Week.

Street Fatalities Increase for 1917.—The National Highways Protective Association has issued its annual report showing that there were 837 deaths on the streets and highways of New York State, including New York City, during 1917, as compared with 729 deaths for 1916. In the State of New Jersey during 1917, 245 persons were killed by automobiles, an increase of only 20 over the preceding year. The increase in the percentage of deaths from street accidents was not as great in Massachusetts and Connecticut as in New York. Col. Edward S. Cornell, in commenting on the facts brought out by the report, states that there has been an increase of about 100 per cent. in the fatalities in New York, and points to the fact that there has been no legislation of importance enacted in New York State with a view to putting a stop to automobile accidents. In contrast to the large number of automobile accidents, it is noticeable that grade-crossing accidents do not increase at the same ratio as other highway accidents, there having been 98 persons killed at grade crossings in New York State in 1917, as compared with 82 in 1916 and 78 in 1915.

Office of Coroner Abolished in New York.—With January 1, 1918, the new law abolishing the office of coroner in New York and substituting that of chief medical examiner went into effect. Under the new law the police court, the district attorney, and the chief medical inspector do the entire work formerly performed by the coroners. Investigation will be made before the police magistrate in the district in which the case occurs, without jury. The chief medical inspector will receive reports from his deputies, these deputies taking the place of the old coroner's physicians. The deputies will take such cases as warrant it before the police magistrate. The new method of dealing with the cases that formerly required the services of a coroner will save time, energy, and money. Dr. Patrick D. Riordan, formerly a coroner, has been appointed chief medical examiner for New York City pending a new Civil Service examination of applicants for the position.

New York Health Department Regulates Laundries.—A report published some time ago by the Health Department gave the results of a sanitary and bacteriological investigation of the laundries of New York City. This study showed clearly that there was need of the adoption and enforcement of definite regulations in order to safeguard the health of those engaged in the laundry industry and of the public at large. Definite regulations were adopted by the Board of Health on December 19, 1917. These regulations relate to the character of the floors, light, and ventilation of the laundries, require the provision of suitable water closet accommodations, and of safety devices on all machinery. A part of the regulations deals directly with the methods of handling the clothing.

The Federation for the Support of Jewish Philanthropic Societies held a meeting at the home of Adolph Lewisohn, in New York, on January 4, at which several hundred directors and trustees of local Jewish institutions were present and discussed ways and means of conducting a campaign

to raise \$4,500,000 during the coming year. The fund hitherto has been supported largely by a few wealthy contributors. It was decided that the increasing burden should be more widely distributed, and to this end it has been planned to conduct a campaign to increase the membership of the federation. Mr. Lewisohn has agreed to increase the amount of his contribution from \$40,000 to \$50,000 provided the membership can be increased to 50,000. A campaign will be begun on January 14.

Dr. Edward F. Brush has been elected Mayor of the City of Mount Vernon, and assumed the duties of his office on January 1. The election will be contested, however, as Dr. Brush's majority was only seven.

Dr. Ellwood R. Kirby of Philadelphia has been appointed physician to the Eastern State Penitentiary of Pennsylvania.

Dr. Alvane C. Seely of Roseburg has been elected president of the Oregon State Board of Health.

The Harvey Society.—The fifth lecture of the series will be held at the New York Academy of Medicine on Saturday evening, January 12, 1918, at 8.30 p. m., by Prof. Henry C. Sherman of Columbia University. Subject, "Food Chemistry in the Service of Human Nutrition."

The Fourth Cuban Medical Congress was held at Havana December 16-22, 1917, with an attendance of over 1,400 members. The *President* of the executive committee was Dr. A. Agramonte; *Secretary*, Dr. Francisco M. Fernandez; *Treasurer*, Dr. J. P. Alacán. The congress was opened on December 16 by the Secretary of Public Health. On December 17 there was a general session. The official subjects treated were as follows: "A Study of the Blood Pressure in Cuba," by Drs. Albertini and Montoro; "Penetrating Gunshot Wounds of the Abdomen and Their Treatment," by Drs. Ortiz and Carrerá; "A Study of the Vital Statistics in Cuba," by Dr. Fosalba; "The Mouth and Diseases of the General System," by Dr. M. Weiss; "Conservative View in Cancer of the Larynx," by Dr. E. Martinez. In the afternoon all the sections of the Congress, eight in number, held their special sessions, a large number of papers being read and discussed. In the evening there was a special session in the Clinical Society, Dr. Aballí reading a paper on "Tuberculosis of Children." On December 18, the day was given to an excursion to the Vento water works, an address being given there by the Director of the National Laboratories, Dr. A. Recio, and a lunch being served afterward. In the evening the sections held their sessions. On December 19, the morning was dedicated to visiting the different hospitals and private clinics, where a series of operations were performed. In the afternoon there was held another general session, in which the following themes were discussed: "Heredity as a Factor in Heart Diseases," by Dr. Filomeno Rodriguez; "Cataract Operation," by Dr. J. Santos Fernandez; "A Comparison Between Excision and Gastroenterostomy in the Treatment of Gastric Ulcer," by Dr. R. Nogueira; "School Hygiene," by Dr. R. Carbonell, and "The Study of the Independent Circulatory Systems in Physiology," by Dr. F. Hernandez. In the evening over 800 members attended the formal banquet held at the Sevilla Hotel. On December 20 in the morning there was another

general session, the following papers being read: "Treatment of Gastrointestinal Disturbances of Infancy," by Dr. A. Aballí; "Obstetric Analgesia," by Dr. G. Cuervo; "On the Right of the Pharmacists Not to Dispense a Prescription," by Dr. G. Fernandez Abreu; "A Study of the Composition of the Blood in Cuba," by Dr. L. Plasencia, and "State Inspection of Animal Foods," by Dr. J. San Martin. In the afternoon several sections had their sessions and in the evening there was a musical recital. On December 21, after the sections had made their recommendations to the Congress, elections were held for the executive committee of the next Congress, the officials elected being: *President*, Dr. José A. Presno; *Secretary*, Dr. Francisco M. Fernandez; *Treasurer*, Dr. G. Fernandez Abreu. On Saturday, December 22, in the morning there was held the last general session of the Congress, at which a number of recommendations were adopted. In the evening the Congress was formally closed by the President of the Republic.

The St. Louis Medical Society has elected the following officers for 1918: *President*, Dr. Elsworth Smith; *First Vice-President*, Dr. P. G. Hurford; *Second Vice-President*, Dr. Rudolph Duhman; *Secretary*, Dr. Arthur Gundelach; *Council*, Drs. M. A. Bloss, P. Y. Tupper, A. H. Hammel, and F. C. Baldwin.

The Southern Surgical Association, at its meeting in St. Augustine, Fla., on December 20, elected the following officers: *President*, Dr. Isaac S. Stone of Washington, D. C.; *Vice-Presidents*, Dr. Legrand Guerry of Columbia, S. C., and Dr. Carey P. Rogers of Jacksonville, Fla.; *Secretary*, Dr. Hubert A. Royston of Raleigh, N. C.; *Treasurer*, Dr. Guy L. Hunner of Baltimore, Md.

The Cumberland County Medical Association, at its annual meeting in Portland, Me., on December 21, elected the following officers: *President*, Dr. C. B. Sylvester of Harrison; *Vice-President*, Dr. Nathaniel N. Marshall of Portland; *Secretary*, Dr. Harold A. Pingree of Portland; *Censors*, Drs. Daniel Driscoll, Frank Y. Gilbert, and George B. Swasey, all of Portland.

The Christian County Medical Society, at its meeting in Hopkinsville, Ky., on December 20, elected the following officers: *President*, Dr. L. R. Woodard; *Vice-President*, Dr. F. M. Stites; *Secretary-Treasurer*, Dr. J. W. Harned.

Ruling to Supply Milk to Children First.—The Local Government Board of England has formulated a ruling providing that local authorities throughout England be empowered to supply milk to nursing mothers, infants, and young children before supplying others. Legislation will be introduced at an early date to give effect to this ruling. In the meantime the board has given consent to local councils incurring reasonable expenditure in providing gratuitously or at cost price milk for infants and children attending welfare centers who are artificially fed and whose parents cannot afford to pay for their nourishment. Many of the large cities have decided to take advantage of the Government concession in the interests of the children. In some cases the loss on the sale of the milk will be met by a special fund and in others by a small addition to the rates.

New York Takes Count of Food Supply.—The

United States Department of Agriculture has designated the Health and Police Departments of the city to distribute and collect the schedules of the food supply in this city. An accurate accounting of all the food stuffs on hand in the 45,000 stores of the city was begun on December 31. This is part of a nation-wide inventory to determine the food supply on hand in this country at the present time.

Continuance of the Mayor's Committee.—Mayor Hylan has requested the Mayor's Committee on Hospital and Medical Facilities, which was organized last year for the purpose of coordinating the hospital facilities of the city for war purposes, to continue its activities, and has asked Dr. S. S. Goldwater to continue to act as chairman of the committee.

Gifts and Bequests.—Mrs. E. H. Harriman has donated the \$500,000 Eugenic Records plant at Cold Spring Harbor, L. I., to the Carnegie Institution at Washington, D. C. The gift includes eighty acres of land, fine buildings, and the valuable records already compiled. Mrs. Harriman has also provided a fund yielding \$12,000 a year to assist in the maintenance of the work. This conveyance is made to insure a permanent continuance of the work.

The Altoona Hospital of Altoona, Pa., is the recipient of a bequest of \$50,000 by the will of Mrs. Harriet Prevost of Philadelphia.

The Babies' Hospital of New York has received a contribution of \$4,000, the proceeds of a musical benefit.

Obituary Notes.—Dr. MOSES J. JACKSON died at his home in New York on January 1, 1918, aged 68 years. He was graduated from New York University in 1892 and served as coroner from 1902 to 1905. He was a member of the New York Academy of Medicine and the Medical Society of the County of New York.

Dr. GEORGE AUGUSTUS OSTRANDER, one of the oldest physicians and surgeons of Brooklyn, died at his home in that city, on December 26, aged 83 years. He was graduated from the College of Physicians and Surgeons, New York, in 1858, and was the first house surgeon of the Long Island College Hospital. He was a charter member of the Medical Society of the County of Kings.

Dr. PAUL S. KAPLAN of New York City died of pneumonia in Beth Israel Hospital, on January 6, aged 70 years. Dr. Kaplan was graduated from the University of Berlin in 1894. He was an exile of Russia, where he had been engaged in revolutionary work and was active in assisting other revolutionists who came to this country. He was greatly beloved on the lower East Side of New York because of the generosity with which he gave his medical services to the poor.

Dr. CHARLES WELLMAN MITCHELL of Baltimore died of pneumonia at his home in that city, on December 28, aged 59 years. He was a graduate of the University of Maryland School of Medicine, in 1881, and professor of pediatrics in that institution.

Dr. ISIDOR JUFE, a graduate of Würzburg University, Germany, in 1886, died suddenly at his home in New York, on December 28.

Dr. MASON LOCKE WEEMS, a graduate of the University of Pennsylvania, in 1890, died at his home in Columbia, Tex., on December 11, aged 50 years.

Dr. HUGO SUMMA, a graduate of the University of Munich, in 1884, died suddenly of heart disease at his home in St. Louis, on December 15, aged 68 years.

Dr. WILLIAM JOSEPH HEARN, emeritus professor of Clinical Surgery of Jefferson Medical College, died at his home in Philadelphia, on December 21, at the age of 75 years. He was graduated from Jefferson Medical College, in 1867.

Dr. WILLIAM L. GALLOWAY of St. Louis, Mo., died suddenly after a surgical operation at Barnes Hospital, on December 15, aged 57 years. He was graduated from the Boston University School of Medicine in 1888.

Dr. JOHN WEAVER LUTHER of Palmerton, Pa., a graduate of the University of Pennsylvania, in 1895, died suddenly in Jacksonville, Fla., on December 28, aged 42 years.

Dr. ALBERT HOLMAN, a graduate of Jefferson Medical College, Pa., in 1881, died of apoplexy at his home in Butler, Pa., on December 13, aged 64 years.

Dr. JOHN B. WILLIAMS of Sterlington, La., a graduate of the University of Tennessee Medical Department, in 1909, died, on December 6, aged 34 years.

Dr. THOMAS BAKEWELL HEGEMAN of Brooklyn, a graduate of the College of Physicians and Surgeons, New York, in 1890, died suddenly, on December 20, aged 59 years.

Dr. JOSEPH PRICE REMINGTON, dean of the Philadelphia College of Pharmacy, died on January 1 at the age of 70 years. Dr. Remington was a member of the revision committee of the United States Pharmacopoeia since 1880, president of the first international pharmaceutical convention in 1893, author of Remington's "Practice of Pharmacy," a Fellow of the Royal Microscopical Society, the London Chemical Society, the Linnaean Society, and an honorary member of twenty-eight foreign and American pharmaceutical and medical bodies.

Dr. CHARLES WINGATE BADEAU, a graduate of New York University Medical College, in 1869, formerly of Passaic, N. J., died at his home in Dunedin, Fla., on January 3.

Dr. AIME M. BLOSSOM died suddenly at the home of her daughter in Montclair, N. J., on December 29. She was a graduate of the Western Reserve Medical College, Cleveland, in 1893. She formerly practised medicine at North Adams and Nantucket, Mass.

Dr. SAMUEL W. TORREY of Beverly, Mass., died after a short illness at the Beverly Hospital on January 1, aged 74 years. He was graduated from the College of Physicians and Surgeons of Columbia University in 1868 and was one of the founders of the Beverly Hospital.

Dr. ALBERT DEXTER KINGSBURY of Needham, Mass., died suddenly while making a professional call, on December 26, aged 75 years. He was a graduate of the Georgetown University School of Medicine, Washington, D. C., in 1869, and a Civil War veteran.

Dr. EARL B. MAXWELL of Findlay, Ohio, died at St. Vincent's Hospital, Toledo, Ohio, of surgical shock following an operation for cervical adenitis, on December 25, aged 30 years. He was a graduate of the Boston University School of Medicine, in 1914.

Correspondence.

THE RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: The Red Cross Institute for Crippled and Disabled Men is organizing in New York City an institution to provide for the physically handicapped the special instructional opportunities which will make the cripple productive, and the special placement facilities which will secure for him the right type of employment.

We are anxious to have referred to us by physicians, particularly in the New York district, but in exceptional cases from other sections of the country, men who would profit by such opportunities as the institute may offer. Almost every medical man will be acquainted with some cases whose need is industrial rather than therapeutic; men who have reached the stage of medical finality, but who will require special training or adaptation to enable them to regain the status of self-support.

The cases which can profit by reeducational work are varied in character. The most obvious are amputation cases, but others readily suggest themselves: severe rheumatism, Pott's disease, paralysis of individual members. For all such cases the benefits of the specialized industrial educator should supplement the work of the surgeon.

We shall appreciate from members of the profession reference of any men to whom we might possibly be helpful.

DOUGLAS C. MCMURTRIE,
Director.

3. The Immoral Woman as Seen in Court: A Preliminary Report.—V. V. Anderson, in his work as Medical Director of the Municipal Court, Boston, has made a study of this type of woman for the purpose of securing facts for orientation. No other basis for selection was required than that each individual should have been arrested for an offense against chastity. An effort was made to examine each woman more or less in the order in which she appeared in court. In all about 100 women were examined. The group selected contained 56 first offenders, 25 second offenders and 19 recidivists. All told, 81 per cent. were either first or second offenders. The average age was 26 years. Alcoholism was found in 34 persons, and drug addiction in 12. Forty-nine per cent. had a mental level below 12 years; 51 per cent. were above 12 years. Forty-eight per cent. were suffering from serious mental handicaps, among which feeble-mindedness ranked highest (30 per cent.). Forty-four per cent. were in poor or bad physical condition from diseases other than venereal, and were in need of medical treatment. More

than three times as many persons who were regularly employed were found in good or fair physical condition as were found in poor or bad physical condition. Anderson considers the restoration of an individual's health might well be one of the most effective means for securing successful probation in her case; for the woman in bad health stood about one-third the chance of the woman in good health for regular employment. Syphilis and gonorrhea were found present in 61 per cent. of these cases. There is no satisfactory method of selecting the particular individuals among known immoral women in court who should and who should not have an examination for venereal disease, for the first offender is just as liable to be infected as the common prostitute. In these cases 66 per cent. of the first offenders were suffering from syphilis or gonorrhea. There is a very high correlation between the frequency of offense and the mental condition of these individuals. Thirty-nine and three-tenths per cent. of first offenders, 47.2 per cent. of second offenders, and 84.2 per cent. of recidivists were suffering from serious mental handicaps. Preventive criminology looks toward the ascertainment of the mental condition of such offenders in advance of their treatment. Taking the group as a whole, about 27 per cent. were in such good physical and mental condition as would enable them, under probation, to return to the community. Twenty-five per cent. were, from a mental point of view, capable of adjusting themselves under well-planned probationary supervision, but were physically in need of urgent medical treatment. Twenty-nine per cent. were suffering from such mental handicaps as to render it unlikely that they would conduct themselves normally in the community unless under very special probationary supervision—supervision suited to the peculiar needs of each case. Nineteen per cent. were in such poor or bad mental condition, and such poor or bad physical condition as to render any attempt at outside adjustment inadvisable, and were in need of prolonged treatment under detention.

3. Exophthalmic Goiter.—Charles Scott Miller states that, statistically considered, diseases of the thyroid body are classified as exophthalmic goiter, No. 51 of the International Classification of the Causes of Death; tuberculosis, No. 34, classified as tuberculosis of other organs; cancer, No. 45, as cancer of other organs; and No. 88, or diseases of the thyroid body. Some conception of the relation of exophthalmic goiter to the other classifications may be gained by comparing the mortality registered for Philadelphia, 1906 to 1915, inclusive. Of all diseases of the thyroid gland from 1906 to 1915, inclusive, the proportion of exophthalmic goiter to other diseases of the thyroid is three to one. Inasmuch as the first class occupies a ratio of three to one to the other classifications, we may take it as an index of the relative mortality due to affections of this gland. Diseases of the thyroid are on the increase, as evidenced by a study of statistical tables. Miller submits a study of 5,230 deaths from exophthalmic goiter. The data cover three groups of statistics and vary somewhat in period of time because of lack of facilities for making a more extensive summary. As a result of this investigation Miller has found that diseases of the thyroid are on the increase for all areas considered. The age period of forty to forty-nine years gives the greatest mortality. The female sex is predisposed. Colored persons are not as susceptible as white persons. The rate for residents of cities is almost uniformly higher than for rural districts. Geographical location has no bearing in goiter prevalence. The water-borne theory of infection has not been satisfactorily demonstrated experimentally or statistically. The same applies to foodstuffs. Judging from the mortality rates, the density of population has little

or no effect on the prevalence of goiter. Geological formation does not affect the prevalence. Miller's conclusions are that the present indications show that goiter is noninfectious and is not caused by a foreign toxin introduced into the body either by food, drink, or other means. Inasmuch as it develops in persons subject to nervous strain, possibly due to their environmental influences and at a period of life when this strain is most acute, and from the indications of overactivity of this gland as presented normally in certain states of health, as pregnancy and menstruation, it is reasonable to infer that all causes point to the development of some poison within the body, due to faulty metabolism. In turn, this faulty metabolism of the body chemistry is influenced by the habits and life of the individual. Therefore the theory of nervous enervation or nervous control, as being directly responsible for the development of goiter in its various forms, and the nervous symptoms manifested in a well developed case are in turn secondary to the reflex effect of the goiter which constitutes a vicious circle.

7. Frostbite as a Predisposing Factor in Carcinoma of the Ear.—Richard L. Sutton points out the fact that areas of skin that have been subjected to frostbite, and especially to repeated frostbite, are abnormally susceptible to cancerous involvement. The parts commonly involved are the ears, particularly the helixes, and the cheeks. A study of forty-six cases of seborrheic keratosis involving the ears and cheeks, occurring during the past year, elapsing Nov. 1, 1917, gives a history of frostbite in twenty-seven. Of this latter number twenty-one presented one or more malignant growths on the affected areas. The majority of the seborrheic keratoses were of the keratoid type. Almost 90 per cent. of the carcinomas were of the basal cell variety. In three instances both the basal and squamous cell varieties were represented. Sutton considers that repeated exposure to very low temperatures tends also to reduce local resistance to the progress of the malignant growth, and thus becomes a factor in prognosis as well as in etiology. He says that the most important prophylactic measure is, of course, adequate protection of the parts commonly attacked. Should keratoses develop, the frequent application of an ointment containing small amounts (from 1 to 5 per cent.) of salicylic acid may be tried. In some instances, double this proportion of sulphur may also be advantageously added. In more advanced cases, suspiciously or frankly malignant, radium usually serves admirably, and possesses the great advantage of leaving the skin in a practically normal condition. In attacking squamous cell growths of the ear, and especially if the associated lymph nodes are involved, radical excision is, in his experience, the method of choice.

1. A Consideration of Recent Serological Work on the Meningococcus.—F. W. Andrews considers that one of the difficulties which beset attempts at the classification of bacteria is the fact that within the limits of what, on general biological grounds, would be deemed a good "species" there are often subspecies or races which differ only in their serological properties. One of the latest organisms to be submitted to close serological scrutiny is the meningococcus, because the recent outbreak of cerebrospinal fever has brought it into prominence. The state of definite knowledge on this subject when the outbreak of cerebrospinal fever in England began to assume epidemic dimensions was briefly as follows: That the causal agent in this disease and in the endemic posterior basal meningitis of infants was the meningococcus. No cultural distinctions could be made between the cocci found in these two affections, nor could any adequate or constant serological differences be established between them. That the meningococcus was divisible into certain subgroups by serological means, and notably by the absorption of agglutinin tests. The number of subgroups was ill-defined, but they appeared to fall into two main divisions, designated by Dopter "meningococci" and "parameningococci," respectively. That from the pharyngeal mucus, both of contacts and non-contacts, cocci could often be cultivated which had all of the biological characters of the meningococcus. In some cases complete serological identity with that organism could be established; in other cases it could not, and some writer stigmatized such unplaced forms as "pseudomeningococci." Andrews gives a résumé of the recent research work done in England, which was prompted by two immediate needs. The first was the provision of an adequate antiserum for treatment, and the second was the provision of means for recognizing the meningococcus, especially in the pharyngeal secretions. The work has been carried out by two independent groups of observers in England, a military and a civil. The military research was conducted under the guidance of Lieutenant-Colonel M. H. Gordon, at the Central Cerebrospinal Laboratory at Millbank. On the other hand, the Local Government Board turned the energies of its bacteriologists in the laboratories at Carlisle Place to a detailed study of the meningococcus from a more abstract point of view, but with special reference to the nature of such cocci from the pharynx of non-contacts. Their material came from the civil population, while that of the military investigators came from the army. Andrews states that the results of Gordon and his coworkers have the advancement in practical measures of diagnosis and treatment, including an improved culture medium adapted for general use and greatly improved methods for the cure of carriers. He refers, chiefly, however, to one branch of their work, that relating to the serological differentiation of meningococci. This was accomplished by means of the absorption of agglutinin method applied to a large number of spinal strains. By this means Gordon separated the strains into four groups, of which two were common and two comparatively rare, though sometimes numerous in certain local outbreaks: he termed them Types I, II, III, and IV. Later experience showed that substantially all the spinal strains met with in military cases of cerebrospinal fever could be referred to one or another of these types, which were very properly regarded as the "epidemic types" concerned in the existing outbreak. It was also shown that by mere agglutination tests, quantitatively carried out, a coccus could almost always be referred to its type, without the necessity for absorption tests. Certain results of much practical importance followed the application of this knowledge. (1) By supplying typical strains to those engaged in making serum for therapeutic use, sera were prepared of greatly increased efficacy in treatment. (2) It was demonstrated by several workers that the type of meningococcus invariably present in the pharynx early in the disease was always the same as that found in the cerebrospinal fluid. This

not only confirms the idea that the disease is spread by means of the nasopharyngeal secretions, but also suggests that every case of cerebrospinal fever arises in a person who is already a carrier. (3) It became possible in many cases to trace the spread of the disease by the identification of carriers bearing given types of the coccus, thus facilitating epidemiological investigations. (4) When the carriers in any locality became too numerous to deal with, a test was afforded by which the carriers of epidemic types of the coccus could be sorted out, as presumably the most dangerous, and separately treated. It will be realized that this serological work had a direct bearing on the immediate control of the disease among the military population, and it was remarkable for the energy and rapidity with which it was carried out. It has been supplemented since by further experimental observations supporting the more or less specific nature of the bodily reactions against the four types of meningococci. Andrews disagrees with Gordon because Gordon speaks of his four types as "species"—a claim which Andrews contends no biologist could support—and excludes from the true meningococci those pharyngeal strains which fail to agglutinate with his four type sera, calling them "pseudomeningococci." During the past two years Andrews submitted the cocci from all cases of cerebrospinal fever at St. Bartholomew's Hospital to agglutination with the four sera kindly supplied him from time to time by Major Hine at Millbank. Twenty-six cases have been in children under 5 years old, and 8 of these have agglutinated so poorly with the sera that he could not regard them as conforming fully to the types—one, indeed, failing to agglutinate at all. Although eighteen of the cases did conform to one or other of the four types, he believes that the meningococcus in the posterior basic meningitis of infants not rarely presents strains which differ from those of the epidemic form of the disease in adults. And if this is so the pharyngeal cocci from non-contacts cannot necessarily be excluded from the group of true meningococci on serological grounds alone. The most which we can legitimately assert is that such non-conforming or imperfectly conforming cocci are not examples of the epidemic types seen in adults during the present outbreak. The Local Government Board were unable to recognize more than two main serological groups of the coccus, and these they found connected by transitional and debatable forms. Andrews further states that so far as the number of groups is concerned the difference is apparent rather than real, for Gordon admits relationship between his Types I. and III., which are often brought down by the same serum, though unequally, and similarly between his Types II. and IV. Andrews offers the following working hypothesis drawn from the present state of knowledge of the meningococcus. The meningococcus is a single, definite species, recognizable by its cultural characters and fermentative reactions, and widely spread as a pharyngeal saprophyte—often a transitory one. In its most primitive form it is a relatively harmless organism, but even at this stage its protein presents two antigenic components. These two components are rarely evenly balanced, and from a serological point of view there emerge two primary races of the coccus—Group I. and Group II.—which correspond to the meningococcus and parameningococcus. The latter term is a misnomer since both are true meningococci. The term pseudomeningococcus is equally erroneous; so far as it has any meaning it signifies a meningococcus of primitive type and low pathogenic power. Under ordinary circumstances the bulk of the saprophytic meningococci of the pharynx are of this low type and mostly fall under Group II., though some are indeterminate. Even in non-epidemic times certain strains of these simple cocci possess sufficient virulence to attack the very young; hence we always have with us sporadic cases of cerebrospinal meningitis. For unknown reasons there is a tendency at times for certain strains to increase in virulence, and this is accompanied by an increased complexity in the structure of the antigen, taking different forms in different strains; it is not known whether the increased complexity is due to the increased virulence or vice versa. The phenomenon is seen in both primary groups, but, on the whole, more in Group I. than Group II., so that, whereas in the less virulent forms Group II. is

the commoner, in the more highly virulent ones the proportions become more equal. When cerebrospinal fever attains epidemic prevalence the virulent strains concerned stand out with relative but not absolute distinctness. The strains in question are possibly different in different epidemics: in the recent outbreak in this country four such strains are recognizable, two belonging to Group I. and two to Group II. The serological recognition of such epidemic types is of manifest importance, both for the preparation of suitable therapeutic sera and for the sorting out of the more dangerous types of carrier.

1. A Contribution to the Study of War Nephritis.—J. Shaw Dunn and J. W. McNee made a study of the cases of acute nephritis met with in the English troops in France since the beginning of 1916. The work has been carried out entirely in the zone of an army, and all of the cases seen in field ambulances and casualty clearing stations have been men from the trenches or from the area within a few miles behind them. The cases have all been observed at an early stage, often within a day or two of the onset of symptoms. They state that severity of weather has had no effect on the returns. Their results show the following conclusions: (1) One of the most characteristic clinical features of war nephritis is the early occurrence of dyspnea, which, though often pronounced, may not be adequately accounted for by any pulmonary condition recognizable from physical signs. (2) The rapidity with which the initial symptoms of the nephritis may subside, after admission of patients to hospital, is remarkable. It is frequently so striking as to suggest that the mere transfer of the patient has brought about discontinuance of the circumstances which caused the disease. (3) From a consideration of the pathological conditions no direct conclusion has been drawn regarding etiology, but some important facts have been ascertained. The visible alteration in the kidneys which is most constant and distinctive is limited to the capillary blood vessels of the glomeruli. The absence of definitely inflammatory reaction in these structures, and the uniformity and selective distribution of the lesions, suggest that they are due to the presence, in the blood stream, of a mildly irritant agent with a special effect on the smaller blood vessels. The edema of subcutaneous tissue, and the vascular lesions in the lungs and the brain are probably due to the same factor. The renal glomeruli may suffer especially by virtue of their specific function in excretion. So far no positive evidence has been obtained which would point to organisms as the primary source of the damage of vessels.

Renal Eliminations.—Ambard of "coefficient" renown, now on the Belgian front, writes upon this subject along the lines followed in a recent Paris thesis, which he doubtless inspired (*Chabamer Étude sur les lois numériques de la sécrétion rénale*). Physiology still contradicts itself as to the concentrating function of the kidneys, for some substances appear in the urine in a concentration lower than that of the blood. In other words, there are substances eliminated which the kidneys are unable to concentrate. In this class, the kidneys behave as an inert membrane. The author terms this form of elimination *diffusion* in contradistinction to secretion proper, in which there is concentration. In order to understand what is meant by this

term, let us ponder upon the normal urea content of the blood, which is 0.35 per 1,000, in contrast with the urea content of the urine, which is say 25 per 1,000. We shall then realize that the kidneys concentrate urea eighty fold. Or let us take a foreign substance, iodine, when given in a dose of 1 cgm. Since the drug reappears in the urine to the extent of 0.35 per cent, the kidneys have concentrated it thirty-six fold. With a substance like sodium chloride, which is an essential part of the plasma, this mode of reckoning is of course inapplicable. Of the 6 per 1,000 parts of salt in blood plasma, only a small fraction can be thought of in connection with concentration of the kidneys. Substances like glucose and albumen are still more difficult to consider. When the former reaches a blood concentration of 3 per 1,000 there is an immediate entrance of glucose into the urine. May we postulate that when the blood albumen exceeds a concentration of 80 or 90 per 1,000 by a certain margin the excess enters the urine? Suppose this margin ends at 110 per 1,000 and that leakage begins at 111. This view seems plausible under certain conditions, but we know that heterologous albumen is excreted not on these grounds but because it is something alien to the blood. In the albuminuria of cardiacs we have a right to think of the elimination of an excess; while in the albuminuria in nephritis we are doubtless dealing with albumen foreign to the economy—excrementitious albumen. The reader will have noted an apparent discrepancy in dealing with the two substances urea and NaCl. Both occur in the blood as constants, yet we have spoken of the entire urea as concentratable, while only a modicum of sodium chloride can be thus spoken of. The differences are obvious for the normal residual urea is not essential to the integrity of the blood. Urea is all excrementitious, yet owing to the conditions under which it enters the blood some of it must always be present therein. On the other hand, NaCl is an integral portion of the blood and only a certain excess can be regarded as excrementitious.

Some Recent Researches into the Functions of the Suprarenal Glands.—Roger calls attention to the old belief that the importance of an organ bears a relation to its size. Galen recognized that so large an organ as the liver must have other functions than the mere secretion of bile. But not until after Addison's time was it fully understood that a small, obscure organ could be of vital significance, although Brown-Sequard showed that extirpation of the adrenals was promptly followed by death. The discovery of this great pioneer was overlooked and years elapsed before it was taken up in earnest. After Oliver and Schaefer had experimented with suprarenal extracts Takamine isolated adrenalin which later was made by synthesis. Trendelenburg showed that the blood normally contains only one one-thousandth of a milligram per liter of this substance, yet this mere trace maintains the blood pressure, and whenever the content is reduced the adrenals contribute a reserve supply. Thus the paralyzing effects of fear are short lived. The author causes embolism in animals by injecting an insoluble powder (lycopodium) into the vessels and shows that the resulting fall of pressure is quickly compensated. Thus in a given rabbit the injection caused a fall of pressure from 100 to 68, but this was succeeded in six seconds by overcompensation to the extent of 164. In fourteen seconds it was down to 146 and fell slowly from this level for about half an hour when it attained an equilibrium of 120-124. Thus the embolism causes a permanent pressure-rise. Roger has sought more light on this phenomenon by extirpating the capsules. With proper technique this either does not affect the blood pressure or at most sends it down to about 80 or perhaps 70. Injection of lycopodium causes a fall of pressure as in intact animals, but this is slight and transitory, as is also the compensatory rise of pressure. The actual result is a progressive lowering without further attempts at compensation. This line of experiment shows that adrenaline acts not only on the peripheral vessels through the vasomotor system but

also upon the myocardium. Studied from all angles from the viewpoint of the double innervation of the heart the author is forced to the conclusion that in nature the adrenal excretes a second substance antagonistic in its activity to adrenalin. Hence injections of pure adrenaline in experimental work are not necessarily analogous to hyperadrenalemia. Alcohol extracts only the adrenalin from the gland while aqueous extracts contain the antagonist substance, which is a constituent of the pigment. The subject has always been an obscure one. Numerous data which bear upon it have not yet been coordinated, and the problem is replete with interest.

Berliner klinische Wochenschrift.

October 17, 1917.

Volhynia Fever.—E. Mosler has studied this affection in a hospital located in French territory occupied by the German army [again demonstrating the defective hygienic control of the German medical staff in the spread of contagious disease]. This disease should be suspected when an affection commences with chills, frontal headache, cramps in the thighs and calves of the legs, and pain in the joints. Pain may likewise be complained of over the tibiae. The clinical picture does not undergo any changes during the evolution of the process with the exception of the temperature chart. The writer insists particularly on the hyperalgesia of certain cutaneous areas, whose distribution would seem entirely radicular in nature, the points the most constantly sensitive being the glabella and tibial crests. The fever may occur in paroxysms of a few days' duration, or on the other hand it may be quite atypical. Treatment by quinine does not give any marked results. Arsenic seems to act more as a tonic than as an antimicrobial agent.

Miner's Nystagmus.—J. Ohm relates the history of this phenomenon and gives some personal charts taken on the nystagmograph. He interprets this nystagmus as an imperfect tetanization of the various ocular muscles. According to the writer's view, this phenomenon would appear to result from a kind of autonomy of the labyrinth from cortical inactivity. The influence of darkness resides precisely in an absence of cerebral stimulation.

Münchener medizinische Wochenschrift.

October 15, 1917.

The Clinical Aspects and Etiology of Volhynia Fever (Werner-His Disease).—F. Munk and H. da Rocha-Lima publish the first part of their paper on Volhynia fever, which is devoted to the clinical aspects of the affection. This disease was first described by Werner and His in January, 1916, and still bears the name of "five-day fever." The symptoms are, roughly speaking, those pertaining to any general infection, but incline more to those offered by malaria. The blood changes are quite insignificant. The specific anatomical lesions belonging to Volhynia fever are as yet unknown. The Weil-Felix reaction (agglutination of Weil's proteus 19) is negative, a fact sufficient in itself to establish the differential diagnosis from typhus fever. No matter what may be the nature of the affection, the writers are of the opinion that it is distinctly different from any other morbid process. The temperature curve is at times paroxysmal; at others it assumes the plateau type. It is not certain that these varieties of temperature belong to one and the same morbid process. The causal factor of the affection, which some writers have believed to be certain organisms transported by lice, is not in reality known. The presence of lice may not be proved, hence the propagation by lice is a questionable matter; the disease occurs quite as often in camps in occupied territories and hospitals as on the Oriental fronts.

[This paper, as well as a multitude of others published in the German and Austrian medical press since the beginning of the war, affords evidence of the enormous number of epidemics which have smitten Germany and Austria and demonstrates the inferiority in hygienic measures taken by their medical staffs.

Typhus fever has been rampant in some of the German concentration camps since as early as the latter part of 1914, when the Germans employed French captive physicians for the care of the patients, in order to escape infection themselves.]

Malaria on the Oriental Front and the Changes It Has Undergone under the Influences of War.—H. Werner considers several points on this subject which occurred to him from experience derived in this domain. Thus the occurrence of successive waves of the infection would seem to indicate transmission of the disease by direct heredity from the progenies of one generation of the anopheles to the following one. The anopheles has a marked predilection for a sojourn in the latrines. It is most resistant to cold, being able to withstand a temperature of 28° to 17° F. The best treatment is the combined exhibition of quinine and salvarsan.

Deutsche medizinische Wochenschrift.

October 18, 1917.

Ethyl Chloride in the Surgery of Warfare.—D. Kulenkampf is of the opinion that 18 per cent. of cases for operation should be anesthetized by this product. An injection of 0.02 centigrams of morphine should be given beforehand, as it shortens and quiets the first stage of the anesthesia by ethyl chloride. The dangers of this anesthetic are of two kinds, to wit: (a) Excitation. This is due to too large initial doses of the drug. When it occurs the narcosis should be stopped and then recommenced, the anesthetic being administered progressively. (b) Deep narcosis is responsible for the great majority of fatal accidents. The writer prefers to continue the narcosis with ether, but generally speaking, every narcosis is advantageously begun with ethyl chloride. Kulenkampf does not employ this anesthetic in cases of cranial injury, in which circumstances local anesthesia should be resorted to, if only on account of hemorrhage.

The Active Treatment of the Neuroses of War.—C. H. Spranger has resorted principally to suggestion during the waking state, combined with the use of the faradic current of sufficient strength to cause some pain. After a period of preparation by a specially trained personnel and the examples offered by subjects who have been cured, the morbid symptoms such as contractures, trembling, paralyses, loss of speech, deafness, etc., may be cured in a single séance. Several treatments have been required in only 9 per cent of the cases. Complete cure has been obtained in 95 per cent of cases out of a total of 322 subjects treated by the writer.

Wiener medizinische Wochenschrift.

October 13, 1917.

Disinfection of the Hands, with Special Reference to War Surgery.—R. von Baracz has noted the divergence of opinion in regard both to the action of alcohol *per se* and to the concentration at which it should be employed. Mechanical antiseptic means destined to remove bacteria on the cutaneous surface are hardly any longer employed. The writer has employed for fourteen years the technique that he saw in use by Weir of New York, which consists in mixing hypochlorite of lime with sodium carbonate (see von Baracz, *MEDICAL RECORD*, April 3, 1897, and *Wiener medizinische Wochenschrift*, 1904, No. 13 and following). The intense bactericidal action is due to the presence of nascent oxygen, which arises from the transformation of hypochlorites into chlorides. The technique recommended by the writer is as follows: A handful of calcium chloride is placed on a plate, and on another some crystals of ordinary soda. After careful cleansing of the hands with soap and brush, a soup-spoonful of calcium chloride and a crystal of soda are placed in the hands. The lime is crushed by the soda with the addition of a little water. A paste then forms on the hands. All this requires about three to five minutes. The hands are next rinsed in sterile water. The odor of the chlorine can be removed by ammonia water, 1 to 5 per cent. The writer recommends this method not merely from the standpoint of surgical asepsis, but also from that of protection of the surgeon himself.

Wiener medizinische Wochenschrift.

October 20, 1917.

The Signification of the Weil-Felix Reaction in the Diagnosis of Typhus Fever.—Schwarzkopf, from the study of thirty-nine cases of typhus fever, comes to the conclusion that a positive Weil-Felix reaction should always cause one to suspect typhus fever as it is only very infrequently negative in cases when the disease is confirmed. Besides, the usual quarantine of twenty-one days seems to the writer insufficient to assure the complete disappearance of the lice and their ova from the clothes. The writer believes that a quarantine of at least four weeks should be imposed.

The Influence of Intragluteal Injections of Protein Bodies on the Evolution of Acute Middle Ear Disease.—M. Rauch, having noted the successful therapeutic results obtained in acute miliary tuberculosis, iritis, and secondary syphilis by this means, has resorted to it with much success in middle ear disease, this being all the more marked the more virulent the infection. Five c.c. of milk injected into the muscles of the buttocks was found sufficient in all the cases treated, the injections being repeated more often in the more serious cases. The mechanism of the action of the milk appears to reside in a stimulation of the formation of the proteoclastic bodies, which results in an elevation of the temperature and at the same time a sedation of the pain. The parenteral administration possesses no prophylactic immunizing action. Out of a total of 41 cases of acute otitis media treated by the writer by means of these injections into the gluteal muscle, operation was necessitated in only 3.

The Treatment of Serious Cases of Polymorphous Erythema with Neosalvarsan.—F. Fischl has noted the excellent effects of this treatment, which he thinks are to be attributed more to the formaldehyde than to the arsenic liberated.

Norsk Magazin for Laegevidenskaben.

November, 1917.

Function of the Liver in Pathological Conditions.—Dedichen divides his long report into sections, each of which has a summary. The first refers to the symptomatic value of urobilinuria in defective cardiac compensation with hepatic stasis. In a series of cases cited by the author urobilin was constantly present in the urine, and also, in one case of ascites, in the peritoneal transudate. Alimentary levulosuria has only a relative diagnostic significance, being more frequent in some hepatic affections than in others. Alimentary mellituria is a very common symptom in hepatic affections, or rather in diseases which present hepatic symptoms. While there are notable exceptions (febrile affections, nervous affections, menstrual disorders) alimentary mellituria implies hepatic insufficiency; although a small quantity of sugar has no diagnostic significance. While levulosuria has little diagnostic value in catarrhal jaundice, notable mellituria is of considerable significance in this connection. Marked galactosuria occurs often in hepatic cirrhosis and in hepatic disorders due to alcohol abuse. From what has been said the author believes that the occurrence of levulosuria is of no value for the diagnosis of obstruction in the ductus choledochus.

Case of Atonic (?) Placental Hemorrhage.—Arnesen relates a case of a primipara aged 26, who up to gestation had been strong and healthy, while gestation had been normal save for initial severe vomiting. Labor was normal and the placenta was expressed by Crédé's method. Blood and blood clots followed the placenta, and there were absolutely no uterine contractions, death seemingly impending from acute anemia. The author was forced to compress the abdominal aorta. Massage accomplished nothing and pituitrin was not available. At the risk of infecting the woman the author inserted his hand into the uterus, and having found no retained placental debris resorted to bimanual compression as recommended by Brandt. After 15 minutes benefit was apparent. The patient also received supporting injections of camphor and gave no further trouble. She had lost from 1.5 to 2 liters of blood. The puerperium was afebrile.

Book Reviews.

GENERAL MEDICINE (VOL. VI OF THE PRACTICAL MEDICINE SERIES, ETC.). Edited by FRANK BILLINGS, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago; assisted by BURRELL O. RAULSTON, A.B., M.D., Resident Pathologist, Presbyterian Hospital. Series 1917. Price, \$1.50 per volume. Chicago: The Year Book Publishers.

The present volume deals with progress in infectious diseases and affections of the gastrointestinal tract, liver, and gall bladder and pancreas. Beriberi is placed under the infectious, although the only abstract on this subject considers it purely a deficiency disease. Trichinosis, which might be regarded as a general infection, is covered under diseases of the intestine. Exotic and endemic infections are not separated. The abstracts are not always so chosen as to represent the advancement of our knowledge. Progress is intimately associated with statistics, and few of the papers quoted have a solid foundation in figures and demonstrations.

ELEMENTS OF FIELD HYGIENE AND SANITATION. By JOSEPH H. FORD, B.S., A.M., M.D., Colonel, Medical Corps, U. S. Army. Approved for Publication by the Surgeon General, U. S. Army. With 152 illustrations. Price, \$1.25. Philadelphia: P. Blakiston's Sons & Co., 1917.

NATURALLY the war has been made the occasion for the publication of a vast war medical and surgical literature. In no branch of medicine has greater progress been made than in that of field hygiene and sanitation. There has been on the French front, at any rate, comparatively little disease and the result has been due to the increased knowledge of the laws of hygiene and their application. Several useful works on military hygiene have been published, but none more useful than the one now being noticed. It deals with all the features pertaining to military hygiene and sanitation and in an especially clear manner. The illustrations and diagrams greatly add to its value.

A TREATISE ON REGIONAL SURGERY. By Various Authors. Edited by JOHN FAIREARN BINNIE, A.M., C.M., F.A.C.S., Kansas City, Missouri. Volume I. Price, \$7.00. Philadelphia: P. Blakiston's Sons and Company, 1917.

EVEN a cursory examination of the first volume of this treatise is enough to convince the reader that the complete work will be one of exceptional value to the progressive surgeon. The aim of the work is to present short treatises on the injuries and diseases of the different regions of the body; and in order that each division might be handled in an authoritative manner, various surgeons specially qualified for the discussion of the subjects assigned to them have been called to the aid of the editor. Thus we find contributions from surgeons in America, Britain, and Australia in the first volume. The work has been under Binnie's general direction; but we learn from the preface that he "has not presumed to interfere in the slightest degree with the material contained in the various chapters." Perhaps it would have been better if Binnie had not held quite rigidly to that position; for while the various chapters contributed by Binnie himself are open to but little criticism, and that generally of the petty variety, those contributed by some of the other authors would undoubtedly have been improved by a little friendly editing on his part.

This first volume was designed to cover the head, bronchial system, thorax, and breast; but a publisher's insert tells us that the section on the thoracic walls, lungs, and pleuræ will be in Volume III, which was intended to cover only the upper and lower extremities. The section on the breast, however, is included in this volume and was contributed by Bloodgood. It is well written and well illustrated, so far as pathology is concerned, but there are no illustrations of operative technique, nor are any operative methods discussed other than that employed by the author. The mere fact that the sections on the thyroid, parathyroids, and thymus are contributed by Charles H. Mayo is sufficient recommendation for this part of the book; and the same may be said for the section on the larynx.

trachea, and bronchi, contributed by Chevalier Jackson. The section on the heart, pericardium, and diaphragm is somewhat disappointing, principally because the author has been accorded insufficient space. The section on traumata of the skull and contents, by Pringle, is of great interest; and it seems a pity that the editor, as he says in the preface, had so much difficulty in securing a suitable authority to write a chapter on diseases of the brain that that subject has been omitted entirely. In the section on injuries and diseases of the face and jaw the reproduction of Murphy's plates showing the technique of operation for organic fixation of the jaw would have added much to the value of the discussion. The sections on diseases of the buccal cavity, and diseases, injuries, and neoplasms of the tongue, by Sir H. L. Maitland, are, in general, admirable; but many will reprobate his advice to excise a piece of a doubtful ulcer of the tongue and submit it to microscopical examination, since this implies waiting for days before radical operation can be performed, if the ulcer is found to be malignant, and practically condemns the sufferer to an early death.

It is impossible to devote sufficient space to criticize or even mention all the various sections; and the reviewer certainly does not wish that failure to mention specific sections be construed as condemnatory. There is considerable overlapping of material, but this is far from being detrimental, since it is so often an advantage to get various methods and viewpoints. The book as a whole is very satisfactory; and since each chapter has been written by a surgeon particularly qualified in that field, it is certain that the methods employed in diagnosis and the technique of operation is such as would be approved by the majority of expert surgeons.

BLOOD PRESSURE, ITS CLINICAL APPLICATIONS. By GEORGE WILLIAM NORRIS, A.B., M.D., Assistant Professor of Medicine in the University of Pennsylvania; Visiting Physician to the Pennsylvania Hospital; Assistant Visiting Physician to the University Hospital; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians, etc. Third Edition, Thoroughly Revised. Illustrated with 110 Engravings and 1 Colored Plate. Price, \$3.50. Philadelphia and New York: Lea & Febiger, 1917.

THE second edition of this work was reviewed in the MEDICAL RECORD barely a year ago, and thus little remains to be said of this the third edition. However, a good deal of new material has been incorporated, and additions of an important nature have been made to those sections in which the functional testing of cardiac efficiency, blood pressure in disease, the effects of drugs, and physiology are dealt with.

The book in its present form is in conformity with all recent advances in the study of blood pressure, and in consequence will serve as a valuable work of reference. It may be said that the illustrations are excellent.

NEW, OLD AND FORGOTTEN REMEDIES. Papers by Many Writers. Second edition. Collected, arranged and edited by Dr. EDWARD POLLOCK ANSHUTZ, Author of "Elements of Homeopathic Theory, Materia Medica Practice and Pharmacy," "Guide to the Twelve Tissue Remedies," etc. Price, \$3.50. Philadelphia: Boericke & Tafel, 1917.

THIS volume is evidently intended in part for the non-homeopathic practitioner, who will find matter of some interest quite apart from Hahnemannism. Thus in some drug provings blood pressures are recorded with sphygmograms, while the drugs were tested upon laboratory animals. The provers are, before some experiments, carefully examined and if unsuitable for experiment are rejected. Those who examine the provers are ignorant of the nature of the drug to be proved. While controls are not mentioned, we understand that they are often used in proving. Along with numerous concessions to scientific medicine, we find plenty of high potency therapy and mental drug pictures, with occasional patronizing flings at the benighted allopaths. Thus the volume has an appeal to both factions of homeopathy, conservative and progressive, and along with the latter to the practitioner of nonhomeopathic affiliations who wishes to have an understanding of Hahnemannism.

Society Reports.

THE AMERICAN CONGRESS ON INTERNAL MEDICINE.

Second Scientific Session, Held in Pittsburgh, December 27 and 28, 1917.

DR. REYNOLD WEBB WILCOX, PRESIDENT, IN THE CHAIR.

Thursday, December 27—First Day.

Address of Welcome.—Dr. JOHN A. LICHTY greeted the Congress in behalf of the Medical Profession of the City of Pittsburgh. He said that they were conscious of the honor conferred by the presence of the distinguished members of the American Congress on Internal Medicine. It would be a pleasure to recount the aims and accomplishments of this congress as well as to speak of obligations to those of its members who had done pioneer and advanced work in Internal Medicine, but he would leave that to be spoken of by others, and would devote the few allotted moments to introduce things medical which were characteristic of the great city to which the visitors had come. The city of Pittsburgh could well be called the industrial center of the world. The present great world crisis had only emphasized this the more. Its mills and manufactories were well known. An inland town, its river harbors received and sent out vessels whose tonnage was equal to that of London and Liverpool combined. To Pittsburgh this was a well-worn, but agreeable expression, and while it might not at present stand the statistical test, it, at least, as Mark Twain says, "sounded well." The city was centrally located. Some one—perhaps a member of the National Geographical Society, or perhaps a statistician of a large insurance company—had said that Pittsburgh was only a night's ride from all the great cities of the United States. The railways and waterways had made its transportation facilities unsurpassed. With such resources and facilities this city, with its surrounding community, had become a veritable workshop for the whole world. The relation of the medical profession to such an important geographical and industrial center had, up to the present time, been largely one of surgical repair, and the city as a result could boast of an amount and quality of surgery which could scarcely be surpassed in any other city of the world. It would be a pleasure to recount the names of men who had made themselves famous in Pittsburgh in the practice of surgery during the past fifty years. It would include such men as Walters, known for his conservative surgery; Sutton, known for his early introduction of the principles set forth by Lister, Pasteur, and Lawson Tait; the McCanns; the Dixons; and the brilliant, beloved, and lamented Stewart. While internal medicine had, in a way, kept pace with surgery, it was only recently that it had come into its own as in the way of preventive medicine, as well as in other well-recognized activities. Pittsburgh formerly had the highest typhoid morbidity and mortality of any city in the United States. Through the direction of the late Eugene Matson, Bacteriologist and Director of the Department of Public Health, the city had laid unsurpassed filtering beds so that the water of the city was now clean, and typhoid had been entirely eliminated. The laboratories of the city were now directed toward the prevention of diseases which were likely to occur in the industries which were here represented. Internal medicine had given valuable assistance in the elimination of the smoke nuisance. Diseases of the lungs in relation to smoke and soot had been particularly studied in the laboratories of the University of Pittsburgh School of Medicine, and in many other ways internal medicine had set about to bring to pass a prevention of diseases, accidents, and calamities which heretofore have prevailed in this community. In conclusion, Dr. Lichty said that the internists of the city as well as the profession at large, would appreciate the benefits which would accrue from the meeting of such a body as was represented by the Congress on Internal Medicine.

Dr. THOMAS REILLEY of New York, in response to the Address of Welcome, said that members of the Congress were all glad to be there. Three or four months

ago it was feared that they would not be able to meet, as the conditions that the war had brought about had made it necessary for many learned societies to close their doors and therefore they were not able to meet. Their president was in the army and matters had gone so far that they were even warned by Dr. Richards that men had better stay at home and help to conserve matters by so doing, and they had also been warned by the Pennsylvania Railroad that it was better to stay home. The railroad even refused to sell return tickets. However, in spite of all this discouragement, the members felt that this meeting was a necessity and that the men who had gone to the expense and trouble that travel in these times entailed were earnest in their desire to attend. The members felt glad to be in Pittsburgh, to show that their interests were not parochial; that these meetings belonged to the East and to the West. Dr. Reilley said that every society that moved out West moved toward progress. Every progressive movement lay toward the West. The very spirit of terrestrial magnetism that was in evidence in Pittsburgh, the fact that they were surrounded by so much iron and steel, must have a physical effect, and therefore, indirectly, a mental effect upon them. Dr. Lichty had pointed out that Pittsburgh was a suburb of Philadelphia, so far as scientific matters were concerned. It could be said that there are numerous large foundations developing, in scientific matters, so that Pittsburgh was awakening to new scientific life. The names of Lichty, Mercur and Johnston were evidences of this. They had made the name of Pittsburgh, in connection with science, a household word. It had been said that there are three classes of millionaires—millionaires, multimillionaires and Pittsburgh millionaires. He felt sure from study of matters in this city that one might also say that there were three classes of internists—internists, great internists and Pittsburgh internists.

Dr. R. W. WILCOX of New York said that last spring when he took service as an officer in the U. S. Army, he feared that it would be impossible for him to come to the meeting. He wrote to Dr. Bartley to prepare a presidential address. Fortunately he was able to be present at the meeting and would have thought it very unfortunate not to be there. However, Dr. Bartley had provided a much better address than he himself could have done.

Vice-Presidential Address.—Dr. E. H. BARTLEY of Brooklyn said that he was very glad that the society had been able to hold this interesting and instructive session. They could not, of course, help a feeling of loss in remembering the thousands of brother physicians who were called away to serve their country. It had been expected that the attendance at this meeting would be much decreased, but it was to be hoped that the interest of the program would counterbalance that possible lack of enthusiasm, due to reduced numbers, which might be felt. It had been deemed best to carry out the program, in spite of difficulties. The membership of the association had been increased by more than one hundred since the previous meeting. It could have been doubled, but the greatest care had been exercised in choosing members whose qualifications should be above reproach. Circularization had been deemed undesirable and the Council had decided to depend upon the judgment of its fellows in presenting the names of suitable men in their localities, so that the best and most representative men should be chosen from every place. In selecting a Council on Internal Medicine, who should study internal and pathological questions, it was felt that members should only suggest the best physicians of their acquaintance—men who had done something for the advance of scientific medicine or for the public. Everywhere internists were scarce on account of the war; but many, because of age or other factors, could not go to the front, and these must do their bit at home—no less loyal and no less willing to serve their country. The work of these internists was of supreme importance to the lives and health of those left behind. In the examination of recruits, statistics had shown that as high a percentage as 60 were unfit for service. This came as a surprise and should be the cause of concern for the future of American manhood and womanhood. When the maimed and shattered wrecks of American manhood began to come back, new problems would arise. There would be a large field for correction of defects in

those who had been found unfit. Those soon liable to be called, those approaching the draft age, would be best treated for correction of defects, when young. Boards of Health and of Education had taken up this question as a function of the State. Labor organizations also had taken the matter up. The medical profession had been remiss in not taking the initiative. It was time now to take some concerted action for the improvement of the health of the masses. There should be more supervision of the young before they came to school age. Statistics showed that in New York there were 20,000 children with more or less serious lesions of the heart. This matter could be handled. There were also various conditions, such as defective nutrition, deformities, endocrinal gland affections, etc., that demanded the attention of the internist, who was the man who usually saw these cases first, before they were sent to the pediatricist. Important discoveries had been made in biological chemistry on the effect of food-stuffs on different animals, but the human animal was not so well studied in this respect as the farm animal. Diseases of nutrition, such as beriberi, pellagra, and scurvy were far from being completely mastered. Poor heredity had often to be overcome in dealing with many children, and in this line much had been accomplished by the use of internal gland substances. It was computed that 8 to 12 per cent. of children needed supervision as regards nutrition. That this was not entirely due to the high cost of living was proven by the fact that the condition was worse in 1916 than in 1917. Many poorly nourished children grew up inefficient. The hope for the country was not in the children of the rich, the unprolific class, but in the children of the masses. Whether these children would be able to maintain the traditions of American life, would depend on how well the medical profession shouldered its patriotic duty. Would America be equal to the task of reconstruction after the war? Efficiency depended upon good health. The great work of reconstruction of the men returning from the trenches would depend upon the efforts of the medical profession and that work would be to a large extent unremunerative. In that national duty the physicians must not be slackers. The medical men who had enlisted had done so at great personal sacrifice and the man who stayed at home was now on trial.

Dr. HEINRICH STERN of New York, the Secretary-General, said that he came to Pittsburgh to show his interest in the Society and because he thought it necessary to push the organization along. He was told that there would not be a meeting, but he had insisted upon it, although the men who were on the committee were in some trepidation. However, he felt that the meeting was necessary at this time. America was only beginning to be involved in the war and next year would be much more deeply in, and physicians ought to be prepared to see it through. This year it might appear that they had not done much, but the Council had had ten meetings. They had added to their list 125 to 130 new members, and he felt that that was very encouraging for a new organization. They mustered about 450 members now. That of itself showed that the Congress of Internal Medicine was a necessity. The work last year was left to individuals, and he might say that Drs. Pottinger and Aaron did the bulk of the work in getting members for the organization. Dr. Pottinger, a born agitator, had seen a great number of people, and the internists had not had to advertise as the College of Surgeons had. Dr. Aaron had made great personal efforts and had got the very best men of the profession. During the past year the Secretary had taken upon himself to publish the transactions. Dr. Cornwall had rendered the most loyal and effective assistance, and thanks were due to him for the results.

Necrology.—Dr. CORNWALL said that deaths that had occurred among members were: Dr. Claude L. Wheeler, editor of the *New York Medical Journal*, a man of delightful personality and very well known in the profession; Dr. Henry L. Coit of Newark, whose name was intimately associated with movements in regard to infant welfare, and who was one of the first of those to advocate and insist upon certified milk; Dr. Le Roy Satterlee was also widely known and much esteemed. He practised as an internist for many years and was one of the teaching staff of the New York Dental Institute.

Election of Officers.—The following were the officers elected to serve during the ensuing year: *President*, Dr. Butler; *Vice-President*, Dr. E. H. Bartley of Brooklyn; *Treasurer*, Dr. Augustus Caillé of New York; *Secretary-General*, Dr. Heinrich Stern of New York; *Assistant Secretary*, Dr. Edward E. Cornwall of Brooklyn; *Councillors*, Drs. Wilcox, Tuley, Sajous, Satterthwaite, and Teish.

Dr. CAILLÉ then moved that a vote of thanks be tendered to Dr. Wilcox for the efficient and dignified services he had rendered to the members as their President. He felt personally that he would very much miss Dr. Wilcox. Dr. Satterthwaite seconded this motion and a rising vote of thanks was tendered.

Dr. R. W. WILCOX said he wished to thank the members for their expression of thanks. He came into this organization at the instigation of the Secretary-General and esteemed it a great honor. Whatever energy he had put into the task he had regarded as only what the organization well deserved; whatever talents he had shown in the execution of his duties he had been glad to devote toward making a success of the society. He felt in this way he had been of service to his city and country.

Symposium on The Roentgen Rays in Internal Medicine: Roentgenology and the Internist.—Dr. CHARLES D. AARON of Detroit read this paper, in which he stated that in his opinion the days of experimentation with the roentgen ray were very far from passed. No sooner was one instrument or one method of technique perfected than a new current of ideas set in and displaced the former ones. Thus, it might be said that the science of roentgenology was still in the phase of active evolution, and would be so until no further advance was possible or until some genius should discover the actual nature of the rays themselves. This was a matter that was still hidden from knowledge. The rapid advances that had been made in this new science had given it the quality of positiveness; thus many of the claims that used to be made for it had been disproved in the light of larger knowledge. At the present time its positive claims could command for it the universal respect of the medical profession. The x-ray diagnosis might be said to be an essential part of the procedure in all the modern and well-equipped hospitals. Not only that, but the office of a modern scientific physician had also its roentgen-ray equipment. The practical value of the x-ray as an aid to diagnosis was thus assured. There were, however, some serious drawbacks to be considered in connection with this subject. Better technique was needed and the necessity of much more thorough correlation between x-ray work and the practice of medicine. A great stumbling block to further progress along this line was the lack of uniformity of details in technique. Take, for instance, the standards in regard to test meals. Not only had different authorities, in different countries, various standards for test-meal procedure, but also different laboratories in the same country were using entirely different methods. Thus no standard of comparison between the work of two men could be set up, as each individual practitioner followed his own ideas in this matter. This want of uniformity was one of the greatest drawbacks to real scientific progress. Laboratories had set up individual standards and were unwilling to compromise or to modify their ideas, and specialists adhered to their own methods and refused to experiment with others equally good. Real progress would only be made when men were willing to sink their individual proclivities and agree upon a universal procedure in order to further scientific knowledge. The claims of roentgenographic specialists at the present time were only to render supplementary service. For instance, in early cases of tuberculosis, before the disease could be detected clinically; or in cases of osteitis fibrosis cystica, the roentgen-ray could aid in diagnosis before a definite clinical picture was found. It should be remembered with regard to the roentgen-ray that the pictures were shadows, not actual pictures of substances, and roentgenologists could not claim that this evidence took the place of clinical facts. Not only was it necessary for the roentgenologist to know clinical data, but, to be well equipped for his task, he must have a knowledge of histology, of pathology and of microscopical anatomy. Without this knowledge he would be unable to

interpret the plates. It should be further stated that roentgenography had two separate and distinct sides. The expert roentgenologist interpreted the findings, but he had also to have expert technical assistants to make the plates. Very few physicians were able to interpret the plates properly because they lacked the technical knowledge. An hour-glass stomach was easily discoverable at autopsy, or at operation; but there were conditions, such as cholecystitis, appendicitis, or stomach conditions, which gave the same symptomatology. In these cases the roentgenogram could make the differentiation. The roentgen diagnosis had its limitations as well as its possibilities. In interpretation the details of the position of the patient and of the tube should be taken into account. If standardized technique were employed, it would do away with many uncertainties, as at present the personal equation was largely a deciding factor in *x*-ray interpretations. When the work was once placed on a standardized basis, results could be compared and reported. The object of the paper was to call attention to general principles, rather than to details. It was felt, no doubt, by practiced workers that their experience was not matured enough at the present time to formulate irrevocable plans; and this could only be done finally by the universalization of technique in the practical application of the art.

The Roentgen Rays in the Diagnosis of Diseases of the Thoracic Cavity.—Major GEORGE C. JOHNSTON of Pittsburgh read this paper. He said that the subject had been "wished" upon him without his choosing it. It was one upon which many books might be written. He felt that in making examination of the chest it was wise to proceed according to certain routine, which should be followed in every case. The roentgenologist must not be misled by the history of the case. The surgeon could open up and find out what was there, but not so the medical man. Routine examination should comprise: (a) heart: size, shape, position; (b) aorta: size, shape, position; (c) lungs: condition of apices, etc.; (d) diaphragm: degree of excursion; (e) mediastinum: tumors, adenopathy. In regard to the heart, this should be examined by the internist first. The *x*-ray was of use in showing the condition of the aorta, and in diagnosing pericarditis with effusion. Difference should be noted between the hypertrophied heart and the dilated heart; the former was working while the latter was simply taking up room. The drop-heart was often shown by the roentgenogram. This was simply an indication of a general visceroptosis and was common in the individual with the long trunk. It had no pathological signification. The "transverse heart," on the other hand, was a menace. It was seen in "stomach athletes" who did wonders at banquets and those in whom the abdomen was larger than the chest. Displacement of the heart was often found. Attention to aortitis could be called by the *x*-ray, and then fewer aneurysms would occur if this were done. With regard to the lungs (b), there were many characteristic signs to be noted. An increased radiability suggested tuberculosis. A decreased radiability, surrounded by area of increased, denoted abscess cavity. In pneumonic conditions there was first shown a light shadow over one lobe, then increase in pleural shadow; in later stages the diaphragm excursion visibility was lost. This latter sign gradually returned as resolution took place. In bronchopneumonia, on the other hand, the excursion of the diaphragm was unaffected. In pulmonary edema a very unusual appearance was noted; all the chest landmarks were lost. In lung sarcomata, globular masses were seen invading the lung tissue; the appearance was very striking. Carcinomata of the lung resembled lung suppuration; it might be noted that carcinomata of the lung were never primary. Primary foci were always to be found elsewhere in the body. In considering the pleuræ it might be stated that a *visible pleura was always pathological*. Normal pleuræ were never seen. If seen, there existed either pyo-, hydro- or pneumothorax. As the pleura filled up with the fluid, the lung retracted. With pus the shadow was darker, as pus was more opaque than water. The diagnosis between complete unresolved pneumonic consolidation and pleural effusion was impossible to make by the *x*-ray. In regard to pulmonary abscess, this rarely reached the thorax. The dark shadow of pyopneumothorax changed shape with the position of the

patient. Knowledge of pathology was a necessity to the roentgenologist, because in all roentgenography of the chest the differentiation was to be made in terms of pathological entity. The more experienced the radiographer, the less he would care to attribute the findings shown by the *x*-ray to invasion by the bacillus of Koch. The speaker said he would care to make a positive diagnosis of tuberculosis only in the most advanced cases. He did not think that one could recognize any particular pathognomonic signs attributable to the bacillus of Koch, but there were certain characteristic changes which radiographers had learned to expect to see and which were attributable to the pathology of the disease. One of these was the "fan," described by Dunham; in early and slight lesions, where a low-grade inflammation was spread by continuity of the mucosa, the fan appeared wide open and distinct. Areas of active tuberculosis, on the other hand, appeared smoky, foggy, and indistinct. The patient was not necessarily very sick in tuberculosis. He could have many tubercle bacilli and not know it; but when lung suppuration was present the patient was very ill indeed. Foreign bodies usually appeared to get behind the shadow of the right bronchus, with the physical "cussedness" of inanimate objects (Newton's fourth law) so that they could not be seen. A *unilateral* bronchial asthma, however, was invariably the sign of obstruction by some foreign body. The speaker had detected in one patient a paper clip, which had been imbedded for 20 years. Such obstruction by foreign bodies was apt to produce in the first few hours an emphysema, but in later stages an atelectasis was present. In conclusion the speaker said that radiography should be correlated with internal medicine, with the object of obtaining all possible evidence in any given case, before making a definite diagnosis.

Roentgen-Ray Diagnosis of Abdominal Diseases.—Dr. WILLIAM A. EVANS of Detroit read this paper. Dr. Evans said that he felt that the present methods of roentgenology were far from perfection and that he addressed the meeting in a spirit of humility. He would speak of general principles rather than deal with one particular organ. In radiography both the fluoroscopic and radiographic methods should be used and the patient should be rayed in the upright as well as in the horizontal position. In some cases reflex irritation was produced from abdominal conditions and the patient could not be put in the upright position. In regard to various organs, pancreatic disease was difficult to study on account of the structure of the pancreas; it was often confused with gallstone disease. In regard to the liver, enlargement of this organ could be detected by the roentgen ray. With the gall-bladder, until recently, only clinical evidence was considered positive. The *x*-ray often gave negative findings even when gallstones were present. This was found to be due to the fact that unless the stones contained 2.5 per cent. or more of lime they were not shadowed by the *x*-ray. In regard to other organs, the distended spleen could be detected, pathology of the stomach shown, and adhesions of the small intestine, colon, and other viscera studied. In the study of the urinary tract, the *x*-ray was not of as much use in the detection of calculi as in delineating the general condition of the tract. In this case the clinical symptoms of pain were not reliable, as frequently with bilateral calculi the pain was only felt upon one side. In the condition of subphrenic abscess the kidney outline was not present. In conditions of urinary disturbance the plates of the mid-ureter region should be examined for spinal changes. These were often associated with urinary calculi. Any pathology of the spine which would cause inflammation of the urinary tract would produce reflex symptoms. In regard to roentgenology of the gastrointestinal tract, radiographers should come to some agreement in order to standardize the opaque meal. Some authorities felt that there was no objection to a single meal, but that the double meal containing salts interfered with functional results and tended to affect the reflex. There was perhaps good ground for this contention. The two-meal advocates, however, stated that the terminal ileum should not be emptied. If, however, the examination could be made within 12 to 14 hours, this difficulty would be overcome. The surgeon had an easier opportunity for examination than the internist in these cases.

The physician, however, was used to questions of diagnosis. The radiographer should report his findings to the internist and make suggestions, but should not attempt diagnosis unless familiar with all the data in the case. In some cases perhaps, such as carcinoma of the stomach, the radiographer could make the diagnosis before the internist. He could differentiate between carcinoma of the stomach and syphilis. Writers were disagreed as to whether bismuth retention in the appendix was pathological or not. However, disease of the appendix was often merely a complicating symptom of colon involvement. The association of the two conditions was very common. In such a short paper it was impossible to do justice to such a wide subject, but a point to be emphasized was that the roentgenologist should learn to correlate his findings with the clinical data of the internist. The roentgen examination should not be postponed, and in this way the best results could be obtained.

The Value of the Roentgen Ray and Radium in the Treatment of Internal Disease.—Dr. RUSSELL M. BOGGS of Pittsburgh read this paper. Dr. Boggs stated that only lately had the internist come to a realization of the valuable help afforded by this agency. It could be stated that in 90 per cent. of the cases of tuberculous adenitis a cure was effected by this means. In exophthalmic goiter and in lymphosarcomata the symptoms were relieved and did not tend to recur. Thus these agents were well worth the study of the internist. They took an important place in treatment of internal disease. They could be applied to blood and blood-forming organs with equally good results. It could be said that today the internist was taking the most important position in medicine. He was beginning to realize the possibility of radiotherapy, which hitherto had been relegated to the surgical side of the hospital. Lately, however, radiotherapy had become a specialty and tended to be handled by experts, instead of, as was unfortunately formerly done, by beginners. Dr. Boggs went on to say that the x -ray affected different tissues differently. Diseased tissues reacted to its influence more quickly than normal tissue. The selective properties of the rays from epithelia formation were shown to be more active on proliferating cells. The cells were affected in proportion to their vitality—embryonic cells being more easily affected. The white blood cells of the body were more susceptible than the red blood corpuscles. The severity of the reaction could be varied according to the amount and type of the rays employed. In exophthalmic goiter an enlarged thymus was often an accompanying symptom, and it was found that 90 per cent. of these cases did not stand operation well. X -raying of the thymus, therefore, should be a preoperative procedure, and it should not be delayed, as very frequently many of the symptoms tended to disappear under medical treatment. These patients were very easily discouraged, and a thorough understanding with them should be arrived at. Raying was not dangerous, or attended with shock, as was surgery, and considerable relief might be obtained before operation. Care was necessary in the raying treatment of exophthalmos, as the patient often passed from the state of hyper- to that of hypothyroidism, and heavy raying was here contraindicated. Results with radium, the writer said, were about the same as with the x -ray, but radium could be easier employed without moving the patient. One of the first symptoms of amelioration was the decrease in pulse rate, and as stability of the pulse was very important, considerable help had been given. Nervous symptoms tended to disappear entirely. There was reduction of the gland in one-half to two-thirds of the cases. After the secretion was reduced to normal, treatment must not be carried to the point of producing myxedema. Often psychic improvement, in symptoms attributed to character, was noted. Exophthalmos was the last symptom to show improvement. There was need for competent knowledge of the physiology of the ductless glands on the part of the physician treating these cases. In regard to other glandular involvement, tuberculous, syphilitic, sarcomatous or that of Hodgkins' disease, the gland in Hodgkins' cases tended to disappear, and also to recur more quickly than others under this treatment. The glands in all these diseases could be controlled for a long time. Large glands

were more easily affected, as the tissue was of lower vitality. Perhaps, in these cases, an autogenous vaccine was set free and tended to effect a cure. In tuberculous adenitis the glands often improved so much that operation was unnecessary. In leucemia, the end results were often unfavorable, though at first the treatment appeared to be beneficial. In all cases treatment must be persistent, and the most successful were those in which it was carried out with thoroughness. As a general rule the x -ray was applied more successfully to cases with bone involvement and radium to those attended with involvement of the spleen and glands.

Dr. E. H. BARTLEY of Brooklyn said that he noted a remark of Dr. Johnston to the effect that he had never come across a case of primary carcinoma of the lungs. Dr. Bartley said he himself had come across a case, some two years previously, which, in spite of all investigations for a primary focus elsewhere, appeared to be a primary sarcoma originating in the bronchial gland. A thorough examination was made at autopsy and no other point of involvement was discovered. He could not say whether this was very rare, but it seemed worth while to mention it in connection with the paper read by Dr. Johnston. In regard to the question of the x -ray in the diagnosis of pneumonia, Dr. Johnston had mentioned central involvement. Dr. Bartley said he was interested in cases of pneumonia occurring in children. In this type the disease certainly did begin at the periphery and extended to the hylus, though the speaker was not prepared to say that it did so in adults. In children the physical signs occurred only when the disease reached the bronchi. There was no such thing as central pneumonia. The x -ray showed that the disease began at the pleura and extended inward. Dr. Bartley said he did not know why, in these so-called central pneumonias of adults, there appeared evidences of delirium and toxemic conditions. Often these cases ended fatally without diagnosis, but were supposed to be central pneumonias. The x -ray should be of aid in determining pneumonia when physical signs were absent.

(To be continued.)

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Joint Meeting with the Philadelphia Roentgen Ray Society, Held Wednesday, December 12, 1917.

DR. MOSES BEHREND, VICE-PRESIDENT, IN THE CHAIR.

Our Preparation for the X-Ray Work of the War.—Major ARTHUR C. CHRISTIE said that more than one-tenth of the total number of physicians in this country have received commissions in the Medical Officers' Reserve Corps. The American Roentgen Ray Society had been one of the first of the national societies to prepare its members for the inevitable struggle, having carried on a propaganda in military roentgenology months before war had been declared. From information from those returned from active service the Surgeon General's Office had decided that the x -ray work in all military hospitals should be directly in charge of medical roentgenologists. To this end schools for instruction in military roentgenology had been organized in nine different cities. Instructors had met in New York for conference and formulated a course of instruction to be followed in all schools. The instructors were all commissioned in the Medical Reserve Corps and assigned to duty for this special work. Selected students, also commissioned in the Reserve Corps, were ordered to report for instruction. Special training in military roentgenology had been found to be invaluable. About 200 men, it was stated, had finished their training at these schools, and some of them were already in France; others at the base and general hospitals in this country. At the school in New York City, where the work of instruction had been concentrated, all of the various types of apparatus adopted for use in the Service had been assembled and were being operated. The present plan for the instruction included a preliminary course at one of the Medical Officers' Training Camps, located at Fort Oglethorpe and Fort Riley. Roentgenologists would now enter the Service through these training camps, and after one month's instruction in

the general training would take another under an experienced instructor sent for such purpose. Those then considered eligible would be sent for final training to the school in New York. In the absence of precedent for guidance, it had been deemed wise in the course of instruction to standardize the methods of *x-ray* men of considerable experience in general *x-ray* work. With the present established curriculum it was believed that a sufficient number of men could be prepared for the *x-ray* work of the war. Major James T. Case, who was in charge of *x-ray* work with the American expeditionary forces, it was said, would be in conference with the instructors in this country in order that the methods adopted might be made applicable to conditions at the front. The work of instruction would now also be greatly facilitated by the publication of a Manual of X-Ray Work. It had been found necessary to train, in addition to the medical men, those engaged in the purely technical part of the work. For this duty men had been drawn from the enlisted personnel of the medical department and given a course of training at the Army Medical School in Washington. Men with factory experience to do the work of installation and repair of highly specialized apparatus had been commissioned in the Sanitary Corps. An important addition in the perfection and standardization of apparatus was said to be the "bedside unit" for the *x-ray* examination without removal of the patient from the bed. This was particularly applicable in fractures of the hip, thigh, and chest. This unit had been developed by Major J. S. Shearer, S.C., Professor of Physics at Cornell University, who was now at the head of the teaching force at the School for Instruction in Military Roentgenology in New York City. A special radiator type of Coolidge tube developed by Dr. Coolidge for use with the army portable apparatus had been made use of by Major Shearer for the bedside unit. The necessity for a readily portable and reliable *x-ray* apparatus had been met by Dr. Coolidge, and a description of the outfit would be published shortly by him. Other developments in accessory apparatus included the construction of a table, the top of which was made of "bakelite," a substance made in connection with the construction of aeroplanes; also a stereoscopic fluoroscope, designed by Captain Caldwell. This, Major Christie said, they expected to be one of America's great contributions to the work of the surgeon in the alleviation of the wounded of the war.

Dr. LAWALD presented the lantern slides of a case of congenital dilatation of the colon in a child of seven years. From a roentgenological standpoint he asked Major Shearer to explain why the shadow of the liver could not be seen through the gas area, although that organ was in its normal location.

Major SHEARER said that the presence of gas in any considerable amount displacing denser material always made it possible to have local overexposure, so that this portion of the negative on full development would be so black as to exclude vision of all details. In these cases it was quite desirable to have the fluoroscopic examination, in which it is generally possible to determine the presence and mobility of gas, which then shows as a very bright spot on the screen.

Pyeloscopy and Pyelography in the Differential Diagnosis of Renal Conditions, with Special Reference to Calculi.—Dr. WILLIS F. MANGES, President of the American Roentgen Ray Society, used the term, pyeloscopy, to describe the fluoroscopic observation of the flow of the opaque solution into the kidney pelvis and calices. By the combination of pyeloscopy and pyelography it was hoped to show the importance of differential diagnosis in renal conditions, and especially in the case of renal calculi. The radiologist, he said, must depend upon the cystoscopist to catheterize the ureters and manipulate the apparatus for the injection of the opaque solution. Pyeloscopy and pyelography were to be regarded as supplementary to clinical and other laboratory methods of diagnosis, including radiography, and as especially valuable in cases in which the different phases of diagnosis are not clear. One of a number of interesting lantern slides showed an unusual point in differential diagnosis. The case presented a mass in the right upper abdomen having the size, shape, and firmness of a kidney. Many of the symptoms, especially those of pain and tenderness in the loin, were referable to the

kidney. With one hand on the abdomen and the other on the back the mass could be felt by both hands and was rather freely movable. A definite shadow appeared on the radiograph, having a shape similar to that of the lower pole of a kidney, but perhaps more dense. During the pyeloscopy examination the mass could be felt and its shadow seen on the screen, so that with an opaque solution in the renal pelvis visualizing the kidney, it was possible to observe the mobility of the mass and also that of the kidney pelvis. The kidney could not be displaced by palpitation, whereas the mass could be moved more or less freely; it was clearly on a plane anterior to that of the kidney and moved toward the median line to such an extent that the outermost point of the kidney calices appeared beyond the mass. The last mentioned observation was clearly demonstrated on the slide. At operation in this case a pendulous and greatly distended gall bladder had been found. In the author's opinion, pyeloscopy should be practised whenever the kidney pelvis was to be injected for pyelographic purposes. Among the advantages of the process were removal of danger of over-distention, visual control of the flow of the solution, and the possibility of making the pyelogram at the proper time.

Treatment of Epithelioma with Roentgen-Ray and Radium, Showing End Results.—Dr. GEORGE M. MCKEE of New York City presented this communication, which was illustrated with lantern slides.

Major WILLIAM H. STEWART of New York gave a lantern slide demonstration of obscure conditions in the epigastrium. A case of special interest was one of syphilis of the stomach.

Major JAMES T. CASE, returned from his work with the American expeditionary force, expressed his satisfaction at the progress made by the roentgenologists of America. The needs emphasized by his work in France he had found to be met beyond his expectation. The Manual of X-Ray Work was as nearly ideal as it was possible to be. The relationship between the roentgenologist and the surgeon brought about by the war had made possible a very admirable type of team work. Such adaptation of roentgenology to medical cases he thought would also be brought about.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

INJURIES OF THE FACE AND JAW AND THEIR REPAIR, AND THE TREATMENT OF FRACTURED JAWS. By P. MARTINIER, DR. G. LEMERLE, and translated by H. LAWSON WHALE, M.D., F.R.C.S. 345 pages. Illustrated. Price, \$1.75. Published by William Wood & Company, New York.

THE FUTURE OF THE DISABLED SOLDIER. By C. W. HUTT, M.D., Cantab.; D.P.H., Oxford. 199 pages. Illustrated. Price, \$2.00. Published by William Wood & Company, New York.

NERVE WOUNDS. By J. TINEL. Preface by Professor J. DEJERINE. Authorized Translation by FRED ROTHWELL, B.A., Lond. Revised and Edited by CECIL A. JOLL, M.B., B.Sc., Lond.; F.R.C.S., Eng. 317 pages. Illustrated. Price, \$4.50. Published by William Wood & Company, New York.

TECHNIC OF THE IRRIGATION TREATMENT OF WOUNDS BY THE CARREL METHOD. By J. DUMAS and ANNE CARREL. Authorized Translation by ADRIAN V. S. LAMBERT, M.D., with an introduction by W. W. KEEN, M.D., LL.D., F.R.C.S. 90 pages. Illustrated. Price, \$1.25. Published by Paul B. Hoeber, New York.

TREATMENT OF INFANTILE PARALYSIS. By ROBERT W. LOVETT, M.D. Second Edition, Revised and Enlarged. 171 pages. Illustrated. Price, \$1.75. Published by P. Blakiston's Son & Co., Philadelphia.

THE SURGICAL OPERATIONS ON PRESIDENT CLEVELAND IN 1893. By W. W. KEEN, M.D. 52 pages. Published by George W. Jacobs & Co., Philadelphia.

THE NATIONAL DANGER FROM DEFECTIVE DEVELOPMENT OF GROWING CHILDREN IN TIME OF WAR.*

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

THE widespread effect of war upon all the component parts of society is manifest to all. Some of these effects are temporary, but others threaten to become permanent. Among the latter the influence of war upon children forms a most important factor. Already in European countries such condition as a marked increase in illegitimacy, juvenile delinquency and dependency are causing grave concern to thinking statesmen. The most immediate danger probably falls upon growing children, who, from actual poverty or scarcity of food, may fail to secure proper nourishment. Under-nourishment is here liable to result in an undevelopment that may be permanent. As the child is the best and most lasting asset of the State, this is unfortunate both in time of peace and war. As for the latter, we must remember that children form the great second line of defense in case of future trouble. For all the exigencies of life, strong, well-nourished children are required and everything possible should be done to secure their normal development.

Public attention is called to this problem from time to time and sensational or alarming statements are occasionally made. During the year 1905 a writer and student of poverty made some disquieting reports as to the extent of destitution.¹ Shortly afterward, a government official was reported to have said that 70,000 public school children in New York went breakfastless to school. This alarming statement created a sensation and was published through the country as an ascertained fact. So great was the desire to get at the truth of the matter that a special committee was formed for this purpose. This committee made an intensive study of the life conditions of 1,400 school children in the poorest sections of the city. The homes were visited and all possible means of investigation were utilized by experts. As far as the breakfast was concerned the following facts were ascertained:

No breakfast	0.7 per cent.
Tea or coffee only.....	1.2 " "
Bread and water.....	0.6 " "
Tea or coffee with bread or cake	48.9 " "

*Read before the Pediatric Section, N. Y. Academy of Medicine, Dec. 13, 1917.

The remaining 48.6 per cent. seemed to have had an adequate breakfast, as 14.8 per cent. were reported as having milk and bread or cereals and 33.7 per cent. as having cereal with either meat or eggs. It was thus learned positively that half of these 1,400 children started the day with an inadequate meal. A certain number were improperly fed during the rest of the day as 2.8 per cent. had no meat or eggs, 12.1 per cent. had tea or coffee three times daily, and 28.1 per cent. had these beverages twice daily. The important point, however, was found that poverty alone was not responsible for this defective diet, as only 8.4 per cent. of the families reported earning less than \$10 per week, 5.9 per cent. had more than \$15, 4.3 per cent. had more than \$20, and 1.5 per cent. had incomes of over \$30 per week. Of the children, 10.4 per cent. showed marked malnutrition, but enlarged tonsils and adenoids, bad teeth and swollen glands were very common. Thus 45.5 per cent. of the children had enlarged glands and 74.9 per cent. bad teeth.

Although the food given these children was often unsatisfactory from the dietitian's standpoint, it was only one of the contributing causes of the unsatisfactory physical condition of many of these children. Poor housing, bad street environment, ignorance and faulty management were all factors entering into the problem. Incidentally, it was found that all of the families paid more than one-fourth of their income for rent, thus exhibiting a fundamental economic error.²

A careful study of most social problems shows them to be complex, often depending on very diverse factors. How much physiological ignorance, faulty economic practice or pure poverty enter into the problem of under-nourished children must be studied at each epoch under investigation. In this study of 1905, parental ignorance and lack of proper oversight were more important factors than lack of ability to procure food.

At the present time the rapidly mounting price of all kinds of food due to the war seems to be assuming a more important place in this problem and thus overtopping other factors. Ignorance may still be with us, but if to this is added an exorbitant rise in the price of food the outlook for the badly nourished child of the poor is indeed unfortunate.

A glance at the extent of this rise and then comparing it with the relative increase of wages may throw some light on the present difficulty. The following has been estimated as the increase in price of common foods from 1916 to 1917: Beef, 48 per cent.; lard, 74 per cent.; cheese, 50 per cent.; peas, 104 per cent.; potatoes, 88 per cent.; beans,

55 per cent.; wheat, 76 per cent.; corn, 57 per cent.; oats, 60 per cent.; flour, 85 per cent.; cornmeal, 51 per cent.²

The Association for Improving the Condition of the Poor has found that the actual daily expenditure for food for an adult now calls for 35 cents, with less for a child under 14 years. Their average expenditure at present prices for a family of 2 adults and 3 children amounts to \$8.10 a week. The dietitian of this society has worked out the comparative cost of food representing 65,000 calories for a family of 5 from 1915 to 1917 as follows:

	Total Cost
November, 1915	\$5.84
November, 1916	7.41
March, 1917	8.24
May, 1917	8.40
November, 1917	8.97

This shows a weekly increase of \$3 in two years. The increase in the price of milk in the past year from 9 to 15 cents a quart has already had an influence on the nutrition of many poor children and will have still more effect in the future if steps are not taken to remedy this evil. A survey was recently made under the joint auspices of the Department of Health, the Association for Improving the Condition of the Poor, and the Mayor's Committee on Milk to collect information on this question from 2,200 families, each containing two children under six years of age. In the whole number there were 5,438 children under six years and 2,534 from six to thirteen years. It was found that 1,480 families were getting from 25 to 50 per cent. less milk this year than last owing to the increase in price; 120 families had dropped milk entirely, 73 were substituting canned condensed milk and 1,213 of the 1,480 families were beginning to substitute tea and coffee for milk. The investigators further found that 2,143 children under six years were drinking tea and coffee.⁴ It is not difficult to foretell what will happen to the nutrition of most of these children.

Another way of approaching this question is to institute a comparison between the increase in the price of foods and the increase in wages during a series of years. In the ten years from 1907 to 1916 there was a gradual increase in wages amounting to 16 per cent. in 1916. In the same period there was an increase in the retail price of foods, slow at first, but rapidly increasing to 19 per cent. in 1912, 25 per cent. in 1914, and up to 39 per cent. in 1916. In January, 1917, this increase had reached 56 per cent. and in February 62 per cent.⁵

According to Dunn's Index figures, from April 1, 1914, to April 1, 1917, dairy and garden products increased 84 per cent., meat 46 per cent., and clothing 49 per cent.

Whichever way we approach this question we are confronted by the great disparity between income and increased cost of living. This is unfortunate for all, but bears especially hard on the growing child. We must also remember that increase in wages does not always mean steady or continuous work. Among 372 working men, with a possible yearly income of \$500, only 38 per cent.

of the maximum possible annual income was received and 25 per cent. of these showed bad nutrition; among 566, with a possible income of from \$500 to \$700, 48 per cent. of the maximum income was received and 15.02 per cent. exhibited bad nutrition, and 456 with income of \$700 or over received 61 per cent. of maximum income and only 12.72 per cent. of those had bad nutrition.

It seems to be a rule of all ages that small incomes and poor nutrition usually go together. The Federal Children's Bureau reports that for all live babies born in wedlock the infant mortality rate is 130.7 in a thousand; it rises to 255.7 when the father earns less than \$521 a year or less than \$10 a week and falls to 84 when he earns \$1,200 or more.

Let us now inquire how war prices have affected many of the children in New York. In a report to the Mayor made by the Bureau of Personal Service, the minimum on which a family of five can live in New York is \$980 in 1917, as compared with \$840 in 1915. In 1915, Dr. F. H. Streightoff stated that one-half the married men in New York were receiving less than \$15 a week, while \$17 was the minimum requirement. There is no doubt that the effect of all this upon the nutrition of many children has been marked.

In 1916 there was an attempt at a nutritional grading of 95,030 children by inspectors of the Bureau of Child Hygiene, New York Department of Health. The children were in grades A, 3A and 6A in schools in the Borough of Manhattan and were classified according to the Dunfermline Scale. This scale is divided into four groups, distinguished as follows:

1. "Excellent" means the nutrition of a healthy child of good social standing.
2. Children whose nutrition just falls short of this standard are "good."
3. Children "requiring supervision" are on the borderland of serious impairment.
4. Children "requiring medical treatment" are those whose nutrition is seriously impaired.

The following were the conclusions from this study:

	Per Cent.
Nutrition 1—Superior condition.....	30
2—Passable condition.....	59
3—Poor condition.....	8
4—Very poor condition.....	3
	100

As the enrollment in the New York City Public and Parochial Schools is approximately 1,000,000, if this ratio were general the following figures would be obtained:

1. Superior condition	300,000
2. Passable condition	590,000
3. Poor condition	80,000
4. Very poor condition	30,000

This would show that 110,000 children require attention on account of defective nutrition.

According to the Board of Education the following is an approximate classification of the child population of New York City:

Percentage of
Total Population

Under 2 years of age.....	4.0
Pre-school age, 2 to 6.....	8.0
School age, 5 to 18.....	24.0
In public schools.....	15.0
In parochial schools.....	2.5
In public and parochial schools..	17.5
Elementary schools	16.0
Secondary and vocational schools.	1.5

It will be seen that any percentage referring only to elementary school enrollment will need to be doubled in order to include the pre-school age and the post-elementary school children who are making the transition to industry.

In a recent report by Mr. Frank Manny, all the pupils of Public Schools 40 and 50, 2,538 in number, were examined and classified according to the physician's diagnosis in the Dunfermline Scale as follows:

	Boys	Girls	Both
Nutrition 1.....	13	31	21 per cent.
2.....	49	35	43 " "
3.....	24	24	24 " "
4.....	14	10	12 " "

These are not among the worst conditioned schools, but if further study shows the same relative proportion among the four nutritional grades, 120,000 cases would call for immediate attention and 240,000 would be on the borderline for careful observation.

An interesting study was also made as to the number of children in the families represented by these pupils in connection with their nutritional classification:

BOYS.

	Foreign Born	Native Born	Both
Nutrition 1....	4.5	3.5	3.8
2....	4.2	3.9	4.0
3....	4.5	4.3	4.4
4....	4.3	4.6	4.5

GIRLS.

Nutrition 1....	3.9	3.5	3.6
2....	4.3	4.3	4.3
3....	4.9	4.5	4.6
4....	4.3	4.7	4.6

This shows what would be expected, that the poorer nutritional cases are apt to be found in the large families. The foreign born children, however, give rather a better showing than the native born.

While the exact number of under-nourished children in any locality can after all only be estimated, the study thus far made shows this number to be very large, with a tendency to increase under the present conditions. It seems to be a world-wide condition and will form one of the most disastrous by-products of the great war. Mr. L. Haden Guest says that one in every ten of the children in the English elementary schools are under-nourished.⁷ Sir George Newman concludes that not less than 10 per cent. of the children of England and Wales are under-nourished.⁸ Doubtless the same condition, if not worse, exists in all the warring countries.

It would seem that immediate steps should be

taken to deal with this serious situation. The first effort should consist in an attempted standardization of medical examination records so that data from various sources can be compared. This could be added to the nutritional scale already in use. All possible defects might thus be collected in four groups. The degree of under-nourishment, together with the kind of defects discovered, and the type of care required, would afford an indication as to how the case should be handled.

After a careful study of the number of under-nourished and defective children in any locality, the local authorities should correlate all the existing relief agencies to see that every growing child has sufficient food—if necessary helping and supplementing these agencies. In every case a campaign of education must precede and accompany relief.

HISTOPATHOLOGICAL STUDIES ON
BRAIN ABSCESS.*

By G. B. HASSIN, M.D.,

CHICAGO,

ATTENDING NEUROLOGIST, COOK COUNTY HOSPITAL.

A BRAIN abscess may be looked upon as a foreign body lodged within the brain tissues, and as such it must evoke in them various reactive changes.

Those portions of the brain which are occupied by, or transformed, into pus are, of course, entirely gone, appearing on gross examination as holes, cavities, etc. In such cases the abscess may be walled off from the unaffected brain portions by connective tissue, or a membrane, which is the ultimate result of the reactive phenomena. In other cases, the suppuration does not become localized, is rather diffuse, is not walled off by a membrane, the brain tissue being, so to speak, flooded with pus. In such cases, the reactive phenomena, the defense put up by the brain, will be different and somewhat more complicated than in the former variety. A brief description of the histopathological changes to be met with in either of these types, based on careful pathological study of five cases, will, I think, be of some interest.

To avoid undesirable repetitions I will report but two cases which I consider very typical.

CASE I.—Man, 59 years old, entered Cook County Hospital November 6, 1915, where he died six days later. He took sick suddenly on November 1, 1915, with chills, fever, and headache, accompanied by drowsiness. Five days afterwards paralysis of the right leg developed, followed the next day by paralysis of the right arm, right half of the face and tongue. The hemiplegia was associated with loss of speech and hearing, rigidity of the neck, and severe pains in various joints.

*From the pathological laboratory of Cook County Hospital, Chicago.

The left big toe showed an embolic suppurative focus on November 12, 1915, when the patient died. The temperature ranged between 100.8° and 104°, and the spinal fluid was cloudy with 2800 cells (92 per cent. polymorphs.) per cubic millimeter. The cultures from the blood showed a streptococcus infection, the source of which could not be ascertained. The postmortem examination revealed a chronic suppurative mastoiditis, a chronic otitis media, a septic purulent meningitis, an abscess in the temporoparietal region of the left hemisphere, one in the middle lobe of the right lung, scattered mycotic emboli in both lungs, and numerous intracerebral and meningeal hemorrhages, some of which covered also the cerebellum, pons, but spared the large basal ganglia, the frontal and occipital lobes. The anatomical diagnosis may be briefly summed up as brain abscess, brain hemorrhages, and purulent meningitis.

Various portions of the brain were hardened in 96 per cent. alcohol, formalin, Weigert's mixture (copper acetate-fluor chrom-formalin), and stained with toluidin-blue, Bielschowsky (silver nitrate), methyl green-pyronin, Weigert's fibrin stain and Mann's mixture (Alzheimer's method V).

The pia over the involved areas of the brain appeared even macroscopically thickened and covered with pus. The microscopical examination showed a purulent meningitis, a detailed description of which, together with that of other forms of meningitis, will be reported in a separate contribution. The microscopical changes in the brain tissue proper varied according to the localization of the hemorrhages, pus foci, etc. Those parts that were infiltrated with pus showed under the microscope a great number of pus cells which mainly consisted of polymorphonuclear leucocytes. Where the pus cells were not numerous, where they did not form dense masses, there could be seen large round bodies containing, as a rule, numerous vacuoles separated from each other by delicate, thin, trabeculae and an eccentrically located usually flattened pale nucleus.

The majority of these mononuclear vacuolated bodies were round in shape, of large size, and mostly devoid of any contents. They have been described in many diseases, as all kinds of meningitis, encephalitis, paralytic dementia, etc., under various names, but are commonly known as Mechanikoff's macrophages.¹ Some of the latest observers, as Cerletti,² Fulci,³ call them "vesicular" bodies ("Blasencellen"). These macrophages were to be found, on my specimens, in large numbers *outside* the pus zone, though they were scattered, in small numbers, also *among* the pus cells, from which they could be easily differentiated by their large size, round form, and vacuolated cell body with an eccentrically located nucleus (Fig. 1).

Besides the macrophages, there were quite numerous other mononuclear round elements, much smaller in size than the macrophages and without any vacuoles in their cytoplasm and which appeared pale and homogeneous. The nucleus is often very irregular, biscuit or kidney shaped, contains a network of chromatin threads, and light in appearance.

Some of these mononuclear cells have a cystic protoplasm which may be represented by one large vacuole with a misplaced flattened nucleus. Such cells much resemble a mononuclear leucocyte and were described and thoroughly studied by Maximow,⁴ in septic and aseptic inflammatory processes, under the name of polyblasts.

"These," he says, "are mononuclear round cells described by some observers either as mononuclear leucocytes, in case they are small, or, in case they are large, as tissue wandering cells, or as fibroblasts reduced to their embryonic state. * * * They originate from lymphocytes, may proliferate and show progressive changes. They are active phagocytes, may be round, polymorphous, large or small, may stain dark or light, may show granules in their bodies, are very numerous in inflamed young connective tissue in whose formation they play an enormous rôle." Maximow considers also the macrophages as polyblasts where he includes the fourth variety of elements to be found near the pus area, the so-called plasma cells (Fig. 1).

The latter, on my specimens, could be seen only outside the pus area, between the latter and the pus free zone. They are very typical in appearance, on account of their chromatin rich nucleus,

FIG. 1.—Various cells in the inflammatory area, *p.n.*, polymorphonuclear cells; *plbl.*, polyblasts; *p.c.*, plasma cells; *g.c.*, "gitter cells"; *mcr.*, macrophages.

where the particles of chromatin, occupying its periphery, radiate spoke-like towards the center. The nucleus shows a distinct membrane and is surrounded by a rich protoplasmic metachromatically stained cell body, where it is usually eccentrically located but frequently occupies the center of the cytoplasm and shows a light unstained space, a halo.

The size of the plasma cells was unusually large, the form round or oval, often there were two nuclei, and the latter's chromatin was not in the form of spoke-like arrangement of its particles but in the form of solid lumps. The chromatin particles could be seen in some nuclei breaking through, as if oozing through their ruptured membrane. In many instances, the plasma cells were represented by a mere nucleus, deprived of any vestige of protoplasm, and then hardly could be distinguished from an ordinary lymphocyte. In

some plasma cells the cytoplasm appeared unusually pale, granular, vacuolated, or cystic. In short, the plasma cells showed numerous regressive changes, though the majority of them, as I said, were unusually large and frequently contained two nuclei.

Finally a fifth type of cells must be mentioned, also mononuclears, round or oval in shape, consisting of a network of minute vacuoles, honeycombed in appearance (Fig. 1), with a pale, always eccentrically located nucleus. These cells much resemble macrophags; but their vacuoles are much smaller, are either empty, on alcohol hardened specimens, or packed with fat granules on formalin specimens. Such cells are known as "Gitter cells." They are very numerous around the vessels, are usually gathered in great numbers, pus cells or any other elements being absent near or around them.

These five types of hematogenous elements—polymorphonuclears, macrophags, polyblasts, plas-

The latter could also be found within, in the lumen of the blood vessels, together with erythrocytes, leucocytes, and lymphocytes. The adventitia was not only dilated, infiltrated, but, as a rule, was also hypertrophied, *i.e.* it showed a considerable increase in the amount of connective tissue fibers, which frequently formed bundles, bands, etc. The vessels themselves were very numerous, tortuous, wounded and formed numerous anastomoses. The capillaries were also numerous, many of them showed a scarcity of endothelial cells, were empty, and surrounded by connective tissue cells, spindle-like in shape, with an oblong, flattened nucleus, and processes emanating from the opposing poles, so-called fibroblasts.

Other capillaries exhibited so-called "Sprossen," protrusions of the endothelial wall, and hardly showed any infiltration. These evidently are new formed capillaries.

The vascular changes are very typical, striking, and much more in evidence than those of the neuroglia tissue, of the ganglion cells, and of the nerve fibers. The ganglion cells in the pus area did not show the usual layers of Brodman; in fact, exceedingly few ganglion cells were left, and those that escaped complete destruction were so changed that it often required some diligent search to notice them. They were very pale, homogeneous in appearance, mostly devoid of their processes. Sometimes the cell body was granular, or even transformed into a shapeless mass of minute granules and without a nucleus. The sole sign of a former ganglion cell was, in some instances, the presence of glia nuclei, or glia cells, so-called "Trabantenzellen" occupying the remnants of a former ganglion cell.

Many ganglion cells showed the so-called "Wasserzustand" of Nissl, when the destroyed cytoplasm of the ganglion cell contained a large empty space around the nucleus. The latter was exceedingly poor in chromatin, pale, and rarefied. In short, the ganglion cells showed all possible pathological changes described by Nissl as "acute" and "severe" cell disease and marked neuronophagia.

In contrast with such profound destruction of the nerve cell bodies, the nerve fibers appeared quite well preserved, even in the most damaged areas. They showed a preserved axone surrounded by myelin, though both the axone and the myelin sheath were greatly tumefied and occasionally covered with varicosities. The glia tissue was represented by so-called protoplasm-poor glia cells, also known as "glia nuclei" ("Gliakerne"). The latter were very poor in chromatin, round, with a well preserved membrane, and very pale. Other glia cells showed the well-known ameboid type, and the glia fibers were transformed in the so-called Alzheimer's "füll" bodies. In other words, like the ganglion cells, the glia exhibited marked regressive changes.

Portions of brain that were not directly involved in the suppurative process appeared cribriform, areolar, contained more or less preserved ganglion cells, proliferated glia nuclei, vessels infiltrated with plasma cells, and a great number of newly formed capillaries. In short, they showed an encephalitis. The pathological changes thus involved the ectodermal and mesodermal tissues. The

FIG. 2.—An inflammatory area with thrombosed vessels (a); b, hemorrhagic foci; c, glia cells; d, perivascular fibrin exudation; no membrane formation (microphotogram).

ma cells, Gitter cells—were very numerous in those portions of the brain which were more or less affected by suppuration.

Any other elements, as ganglion cells, glia cells, nerve fibers, either could not be encountered at all, or on suitably stained specimens appeared greatly changed. Thus, frozen sections from the suppurative or purulent zone, stained with Mann's mixture (methyl blue eosin), were instructive.

As the microphotogram (Fig. 2) shows the visual field is covered with hemorrhages and a large amount of vessels in the form of dark islands. The vessels were uniformly thrombosed and enveloped by a more or less extensive network of fibrin, whose meshes, in many instances, could be seen scattered over the larger part of the visual field, and containing a great number of red blood cells. Some of the vessels did not show the perivascular fibrin exudation, but always had dilated adventitial spaces, filled with infiltration cells, which exclusively consisted of plasma cells.

former, *i. e.* the nerve and glia tissues, exhibited marked regressive phenomena that resulted in almost total destruction of the brain tissue and in ameboid transformation of the glia, while the mesodermal tissue showed progressive changes, like neo-formation of capillaries, hypertrophy of the adventitia and proliferation of fibroblasts. In addition, there was a pronounced perivascular infiltration, chiefly with plasma cells, in the presence of numerous leucocytes, macrophags and polyblasts.

The predominance of progressive mesodermal changes was much more in evidence in the next case, where they resulted in a formation of a solid connective tissue membrane.

CASE II.—G., aged 29 years, entered Cook County Hospital March 3, 1916, complaining of headache, weakness and cough. A good history could not be obtained. He claimed having been suffering from a severe headache for nine months. Two weeks after his stay in the

FIG. 3.—An abscess membrane with three distinct layers. *a*, the abscess; *b*, the inner layer of fibrous tissue; *c*, the middle layer; *d*, the external layer; *e*, brain tissue (microphotogram).

hospital he became irrational, toxic, developed a septic state in which he died 18 days after his admittance.

The spinal fluid showed 120 cells per cubic millimeter. The post mortem records were as scanty as the clinical ones. They did not give any information relative to the microscopical brain changes, the location of the abscess, its possible origin, etc., and for microscopical studies there were available but a few pieces of brain tissue, one of which contained an abscess the size of a quarter. The microscopical changes around the abscess proved to be so striking, so typical, that I thought it worth while studying and recording them, regardless of the deficient clinical and gross pathological records.

Between the abscess and the retained brain tissue there could be discerned, even with the naked eye, especially when stained with Marchi, a band of tissue enveloping the abscess and thus separating same from the rest of the brain (Fig. 3). Of nu-

merous staining methods tried the best one proved to be that of Van Gieson (iron hematoxylin of Weigert with fuchsin—picric acid) after previous hardening of the tissues for 24 hours in Zenker's fluid. Frozen, celloidin, and paraffin sections were used, and all of them gave very beautiful and instructive pictures. The pus of the abscess cavity consisted of granular bodies and very few polymorphonuclear leucocytes. The membrane showed three distinct layers. The innermost, adjacent to the pus cavity, was represented by a thin strip of collagenous fibers, running parallel to each other and forming dense, compact bundles of fibrous tissue, without any interspaces, and with very few, mostly obliterated, blood vessels. Very few of the granular pus cells could be found among the inner fibers of this layer, which was followed by a much broader zone that was rich in capillaries, plasma cells, polyblasts, fibroblasts, and peculiar protoplasmic rich cell bodies covered with black granules and a well stained nucleus—probably so-called clasmatoocytes.

A remarkable feature was the presence of numerous transitional forms among all these elements, which commonly appeared unusually large in size. The plasma cells were as a rule quite typical. Scattered around the vessels and among other cells they could be easily recognized by their peculiar chromatin rich nucleus and a large protoplasmic body. Some contained two nuclei which sometimes appeared elongated, rod-like, peripherally located and filled with small chromatin particles, while the protoplasm showed spindle shaped form, resembling the cell body of a fibroblast (Fig. 4).

Other plasma cells while retaining their typical nucleus exhibited an unusually well developed protoplasm with dull branched processes, ameboid-like, with a kidney, or biscuit shaped or slightly elongated nucleus. Such cells much resembled Maximow's polyblasts. The fibroblasts were all well developed, contained sometimes an enormous nucleus, a cell body that also was very large, often reticular in appearance, filled with minute black granules, and provided with distinct processes.

The fibroblasts were scattered singly, or in groups, especially around the capillaries. Their processes sometimes were very long, making an impression of connective tissue fibres, which, however, in this layer were totally absent. The vessels were quite numerous, with very thick, hypertrophied walls, infiltrated with lymphocytes, plasma cells and thickly covered with fibroblasts.

The fourth variety of cells were represented by large cell bodies (Fig. 4) emitting small pseudopodia, granular in appearance, thickly covered with minute granules and a light excentrically located large nucleus. These cells were lying free among the meshes formed by the process of the fibroblasts, seemed to be enveloped by them, fewer in number than the plasma cells and fibroblasts, and were usually seen near the vessels. On my specimens, they appeared much larger than the fibroblasts which, as I said, were very numerous and of great size, with two or three nuclei.

The described fourth type of cells to be found in the second layer of the abscess membrane strikingly resembled the clasmatoocytes as depicted by Maximow in his classical work on inflammatory neo-

formation of connective tissue. The clasmatocytes were first described by Ranvier in 1891⁶ in the femoral aponeurosis of frogs, in thin connective tissue membranes of various vertebrates (frogs, rabbits, guinea-pigs, rats, etc.) and originate according to Ranvier from leucocytes which emigrated from the blood vessels into the interstitial spaces of connective tissue, where they remain as permanent elements and possess secretory properties. Together with the leucocytes they furnish material for pus material. They possess numerous processes which branch, but do not anastomose. Toward the end of their evolution, the protoplasm filaments break up or become dissolved, and "the grains of the secreted material are discharged into the meshes of the connective tissue," where they remain. Maximow proposed to name them "resting wandering tissue cells." On my specimens they appear much larger than ordinary so-called lamellar-flat connective tis-

FIG. 4.—Various cells in the second and third layer of the abscess membrane. 1-2, fibroblasts; 3-6, clasmatocytes; 7-8, plasma cells; 9-10, plasma cells forming fibroblasts.

sue cells and somewhat resemble the "epitheloid and connective tissue" cells as reproduced by Harris.⁸

Ranvier's clasmatocytes were also described by Maximow, as well as by Doinikow⁷ in lower animals, but I could not ascertain whether they were found in normal or pathological human tissues. Therefore I hesitated somewhat in classifying the fourth type of the above described cells among clasmatocytes of Ranvier. Yet, their general appearance is so different from the rest of the elements to be seen in the second layer of the abscess membrane, they so much resemble the ones reproduced under this name by Maximow, that I must consider them as clasmatocytes, and thus admit their possible occurrence at least in *pathological* human tissue.

Especially numerous are they in the third layer of the membrane, the one that borders with the brain tissue proper. This layer shows a well-formed, ripe,

so to speak, connective tissue consisting of fibres. These form meshes filled with the clasmatocytes, large hypertrophied fibroblasts, plasma cells and polyblasts. The plasmacells and polyblasts are less numerous than in the second layer, but still present, mostly around the vessels which showed a well-formed, but infiltrated adventitia. There are to be seen in the layer numerous plasma cells that partly resembled fibroblasts, being evidently in the process of transforming in the latter and connective tissue fibers. (Fig. 4.)

Another peculiarity of the third layer is the presence of enormous amount of black granules, some of which were composed of hemosiderin, and some, as Marchi specimens counterstained with Ehrlich's hematoxylin showed, were fat. The black granules were very numerous around the vessels, but frequently could be found also in the fibroblasts and the clasmatocytes. Glia, nerve fibers, ganglion cells were anywhere absent in the membrane which wholly consisted of mesodermal elements that replaced the brain tissue.

The question arises whence did the mesodermal tissue develop and what produced such powerfully developed fibroblasts, polyblasts, plasma cells, etc.? That the plasma cells are of hematogenous origin, are modified lymphocytes, is at the present admitted by the majority of investigators (Fulci, Cerletti, Maximow, Schaffer⁹); the polyblasts are definitely established by Maximow to be also modified lymphocytes or plasma cells and capable of producing connective tissue. That the clasmatocytes are also of hematogenous origin was already pointed out by Ranvier and admitted by Maximow, but Ranvier denied their ability to form connective tissue which, however, was proven by Maximow to be a fact. In short, the connective tissue develops from leucocytes or lymphocytes and their modified states—plasma cells, polyblasts and clasmatocytes, which elements can be looked upon as embryonic connective tissue. The study of membrane formation around a cerebral abscess, thus, affords excellent opportunities of following up the evolution of connective tissue growth—its embryology. So far, such studies have been carried on experimentally (Ziegler, Maximow, and others). Especially remarkable were the investigations of Maximow, who succeeded in obtaining poor cultures, as it were, of connective tissue elements, by inserting glass cameras, celloidin plates, and tubes, etc., in various animals, as rabbits, pigeons, dogs, etc. He chose places commonly poor in connective tissue, as peritoneum, intermuscular tissue of the abdominal wall, where very little fat and very few vessels are present.

The brain seems to be still more favorable for such studies, and, as the findings in my second case show, the connective tissue does originate from the hematogenous elements—lymphocytes, or mononuclear leucocytes (they are according to Maximow a modification of lymphocytes), plasma cells, polyblasts, and clasmatocytes—as advocated by Maximow, though he did not admit that plasma cells may produce connective tissue.

As neither time nor space would permit of further discussion of this highly interesting and difficult subject, I will have to limit my remarks to what I said, but would like to point out that the three distinct layers with distinct and characteristic micro-

scopical structure do not show in every case. In some cases, there is no distinct membrane to be seen, but a mass of plasma cells, leucocytes, polyblasts, and fibroblasts scattered among congested and infiltrated blood vessels, any collagenous, well formed connective tissue fibers being absent. Much, of course, depends and must depend upon the stage of the membrane formation, upon the severity and the duration of the fundamental disease process.

As the above-mentioned elements, lymphocytes, plasma cells, etc., undoubtedly originate from the vessels, the latter must be looked upon as the source of the new formed membrane, or of the cells that are instrumental in building up a defense for the remaining brain tissue. This defense is here evidently of a character different from that usually to be met with in various other organic nerve lesions (tabes, amyotrophic lateral sclerosis, multiple sclerosis, subacute cord degeneration, etc.). In all those central nerve lesions, where the parenchyma alone is involved, the active rôle in replacing the damaged nerve substance is accomplished by the glia as described by me elsewhere.⁹ The progressive glia changes finally lead to a glia scar formation which scar in brain abscess is formed, not by the glia, but by the connective tissue, or rather by the vessels that furnish material for it in the form of mononuclear leucocytes, or lymphocytes, plasma cells, polyblasts, and clasmatocytes.

Further studies along these lines are absolutely desirable as the subject of histology of brain abscess is the most neglected one in the entire neuropathology. There are but few contributions on this subject available, the best of which are those by Westphal,¹⁰ Kölpin,¹¹ Oppenheim-Cassirer,¹² and Homén.¹³

THE SURGICAL SIGNIFICANCE OF ABDOMINAL PAIN IN CHILDREN.

BY WILLIS E. HARTSHORN, M.D.,

NEW HAVEN, CONN.

AMONG the most common sources of abdominal pain in children should be mentioned the following:

Intestinal disturbances due to indiscreet dieting or to constipation.

Intestinal disturbances due to appendicitis.

Intestinal disturbances due to peritonitis, the etiology of which may be (a) pneumonia, (b) surgical conditions the site of which is elsewhere in the body, (c) empyema, (d) subphrenic abscess, (e) the tubercle bacillus, (f) the infectious diseases, (g) typhoid perforation.

Intestinal disturbances due to volvulus or intussusception.

Intestinal disturbances due to pyelitis.

The attacks of abdominal pain from indiscreet dieting are the most frequently seen and most easily diagnosed. They deserve but little discussion from the surgical standpoint. Associated with frequent vomiting and a high temperature, they respond almost immediately to the proper medical treatment. Another type, however, is that which owes its origin to chronic constipation. The onset is insidious. The pain is constant in character, not very severe, but just sufficient to keep the patient in continuous distress. As is common in childhood, the character of this pain is difficult to elicit except that the parents will usually state that the patient is unable to sleep nights and that the pain has continued over a number of days, being of an intermittent variety, sometimes located in the region of the umbilicus, at other times more general in character. The child is restless, is losing weight and looks poorly. On physical examination there is noted a moderate degree of abdominal distention. The percussion note is tympanitic in character. On palpation there is general abdominal tenderness with perhaps slight spasm of the right rectus over the region of the appendix. Rectal examination is negative. It is very important to make this in the case of children, as tenderness here or the presence of a mass is often sufficient to establish a diagnosis. The tongue is coated and somewhat dry. The facial expression is indicative of a general toxemia. There is a slight daily rise in temperature, intermittent in character. There is a small increase in the leucocyte count with but little increase in the poly-

morphonuclear cells. The examination of the lungs is negative.

A high enema properly given associated with the use of laxatives at once relieves the symptoms. The difficulty in these cases is that the bowels have not been properly evacuated, though there may be a history of frequent enemas given by the parents. The importance of the high enema properly administered is one not thoroughly appreciated. Parents must be instructed definitely how this should be given, otherwise results will not be obtained. At times these intestinal attacks are very severe and difficult to diagnose. This is well illustrated by the following case:

The patient, four years of age, became suddenly very ill. The temperature was 105 deg. There was frequent vomiting. The abdominal pain was of a severe type. It was general in character and at no time localized. There was constipation. The child appeared to be suffering from an infection of a very active character. No improvement occurred even after the bowels had been moved several times and high enemas freely administered. A small amount of reddish material of a foreign character was evacuated, when the temperature at once subsided and a rapid convalescence followed.

To distinguish between the simple intestinal disturbances noted, which are purely medical, and those of surgical significance is often very difficult and puzzles the internist as well as the surgeon. The two extremes are well illustrated by the type of infection which, starting as a pneumonia, develops later abdominal pain considered by the attendant to be due to a pneumococcus peritonitis, but which is really appendical in its origin, with a sequel of a too-long-delayed operation followed by the death of the patient; and those cases of appendicitis which are operated on by the surgeon with the result that a normal appendix is found and the child after the operation runs a typical pneumonia with the added postoperative complications which develop after even the most simple operative procedures in children. In a case of this kind we find that the added strain of the operation is at times just sufficient to turn the scale in the direction of an unfavorable outcome. This is especially true where the pneumonia is of central origin. In both it must be remembered that a high leucocyte count prevails, the amount of this varying with the severity of the attack.

To illustrate, the writer calls to mind a case in which for several days a child seven years of age had suffered from abdominal pain. The temperature range was neither high nor typical. The leucocyte count was low. The pain, though generalized, seemed to focus more in the region of the appendix than at any other point. A number of careful examinations of the lungs by internists on different days failed to reveal any definite or even suspicious signs of pneumonia, and yet at the operation a normal appendix was found and the child shortly developed a pneumonia, central in character, which ran a mild course with a typical temperature and crisis. Fortunately, the patient was at no time in a critical condition. Evidently the administration of the ether was sufficient to light up a process in the lungs which had previously been more or less quiescent.

This case well illustrates the fact that appendicitis in children is difficult to diagnose. It is very rare in infancy. The proportion of cases increases gradually with the age of the child. The greatest care must be exercised in establishing a diagnosis. So many other conditions of a pathological nature in

children may cause abdominal pain that this point must be emphasized. A pleurisy in which the lower intercostal nerves are involved may simulate appendicitis, acute attacks of colic, the distress of intestinal indigestion characterized by a dull aching pain which involves the right lower quadrant of the abdomen, intussusception, which will be reviewed later, and pyelitis, all must be considered and carefully ruled out. Appendicitis is an insidious disease and appears associated with so many different clinical pictures in children that unfortunate mistakes are sure to be made. Every case of acute pain with tenderness localized in the region of the appendix should be classed as appendicitis until this diagnosis is absolutely ruled out by the development of a primary focus elsewhere. If, in addition to this localized tenderness, there are a high differential leucocyte count with an excess of polymorphonuclear cells to the extent of 80 per cent. or over, rigidity of the right rectus, which is real rigidity and not simply spasm, and a mass felt on palpation, the diagnosis can be assured only after the administration of high enemas in order to relieve a possible fecal accumulation in the cecum. It should also be borne in mind that enlarged and inflamed inguinal glands at times complicate the picture.

Operative procedures in children under 2 years of age are not borne well; up to the age of 6 or 7 not so well as in the case of older persons; after this age rather better than in adults. In fact, some remarkable recoveries are seen in children suffering from ruptured appendices associated with peritonitis. One instance is called to mind in which a boy of 12 was admitted with the entire abdomen rigid, having been treated for typhoid fever for eight days. The pelvis was filled with pus, more than 300 cc. being evacuated at the operation; there was also an extensive spreading peritonitis following the rupture of the appendix. The recovery was complete without an unusually long convalescence. The point to be emphasized is the danger of rash operative procedures. Many children do not take ether well, especially if the slightest irritation of the lungs is present. There is a tendency to cyanosis during the anesthesia and the accumulation of a large amount of mucus in the throat and bronchi. This frequently presents a very serious complication, and most careful preoperative examinations should be insisted on. If chloroform is administered while the patient breathes with less effort, there is the constant danger of cessation of respiration and the need of a watchful attitude on the part of the operator which detracts from the concentration on the operation that is so essential to the surgeon. In children, the use of morphine before operation should be avoided as it inhibits the respirations to a dangerous degree and has practically no effect on the accumulation of mucus. Nitrous oxide is not well taken, unless judiciously mixed with oxygen and should be administered only by an expert. In empyema it should not be used, a local anesthetic being far preferable.

Peritonitis in children presents itself in many different phases. It is associated with varying degrees of pain. Primary peritonitis is rare. In the secondary form it is comparatively common. The origin of the infection must be carefully traced. Appendicitis is the most common cause. The colon

bacillus, staphylococci, streptococci and pneumococci are frequently found in cultures taken from the peritoneal content. In cases of perforation from typhoid ulcers, typhoid bacilli may be discovered. Infection of the peritoneum may follow systemic conditions of a pathological nature, such as tuberculosis and syphilis. The acute infectious diseases, such as scarlet fever and influenza, also form the basis for an extension to the peritoneum. The female genital tract offers a not infrequent source of contagion, and occasionally it may follow a meningitis or otitis of pneumococcic origin. Whenever it occurs in children it should not be considered primarily a cause for surgical intervention. Subsidence often follows improvement in the primary infection, though the condition may at the time present a surgical picture of a very acute character.

The symptoms of peritonitis vary in different cases. As a rule, when secondary, its onset is suggested by a gradual abdominal distention accompanied with pain of a general character. This stage may be preceded by much more acute phases, such as acute colic with a temperature of 104° or 105° and a rapid increase in the pulse rate. In this case, the abdomen soon becomes distended and tympanitic. There is considerable spasm of the abdominal muscles. The legs may be drawn up and the facies pinched. This type of case usually runs a comparatively short course and ends fatally.

Peritonitis due to pneumococci is a frequent complication of various systemic infections. Its onset is often somewhat typical. It is usually accompanied with general pain commencing in the epigastrium. This is followed by distention and difficulty in securing a movement of the bowels, owing to the stasis caused by the inflammation of the peritoneum. When this occurs in the latter stages of a severe pneumonia it is often of serious import. At times, however, it is the first symptom of the systemic infection, the actual inflammation of the lungs following this and developing after free catharsis has relieved the abdominal condition. The point to be emphasized is that a careful examination of the respiratory tract should be made a matter of routine when abdominal symptoms of an obscure character appear in children.

A case recently seen illustrates this point. The patient, a child of eight years, began to complain of abdominal distress. Active movements of the bowels did not relieve this and his condition continued to become worse. There was considerable abdominal distention. Careful examination failed to show any localization of the pain. There was no muscular spasm or rigidity. The general condition was excellent. The temperature was ninety-nine. The urine examination was negative. The leucocyte count was 12,000. The tongue was coated, but not dry. The facial expression was practically normal. A careful examination of the lungs revealed rales at the left base which suggested a bronchial pneumonia. This developed later and ran a mild course, the child eventually recovering.

Almost any general practitioner can remember in his experience cases of a similar nature. Often these are so puzzling that the aid of a surgeon is called, and very wisely, to eliminate a possible surgical condition.

Attention at this point should be called to tuberculosis peritonitis. It may be secondary to a general tuberculosis infection or to a localized focus such as the mesenteric lymph nodes; this in turn

may follow Pott's disease of the spine. Primary foci such as a tuberculous knee joint or hip should also be mentioned. The development of this type of peritoneal infection is often insidious. The clinical signs are frequently not clearly defined. The onset is often indicated by a slight daily rise in temperature with gradual loss in weight. The abdominal pain complained of is indefinite in character and is not usually a marked symptom. A physical examination may give no positive signs in the lungs but the abdomen shows a moderate degree of distention. With this distention there is associated the accumulation of ascitic fluid. Diarrhea rather than constipation is apt to be present, or there may be alternating attacks of diarrhea and constipation. As the disease progresses the fluid content of the abdominal cavity markedly increases; this pictures the miliary type. In the fibrous or ulcerative form, the coils of intestines are bound together by adhesions forming masses which can be palpated, indicating the extension of the infection to the intestines, mesentery and omentum. These cases usually run a very unsatisfactory course. There is intermittent pain of a dull aching character with exacerbations as the obstruction of the intestines by fibrous bands or adhesions gradually increases. In the fibrous or ulcerative type, operative procedure is of little avail, except to relieve the obstruction. In the miliary type with ascites section of the abdomen with drainage of the fluid usually gives temporary relief.

Peritoneal infection at times follows as one of the many complications of scarlet fever. Sometimes the pain associated with these attacks is localized and a differential diagnosis between a simple peritoneal infection and that due to actual appendicitis is very difficult. To add to this difficulty, it should be remembered that in scarlet fever there is usually a high leucocyte count. This varies from ten to forty thousand, depending on the severity of the infection, and persists often into the later stages of convalescence. The increase in the polymorphonuclears is relative to the increase in white cells.

A patient recently seen had run a typical scarlet fever infection associated with an arthritis of the larger joints, especially the elbows and knees, during convalescence. A sudden rise in temperature was noted about two weeks after the subsidence of the acute symptoms and the rash. This was accompanied with acute abdominal pain, at first general and later fairly well localized in the right lower quadrant of the abdomen. At the same time there was noted an exacerbation of the joint symptoms. A leucocyte count showed 18,000 leucocytes with 80 per cent. polymorphonuclears. This made the diagnosis a difficult one, as the patient was in a rather septic condition and the prognosis following operative procedures would have been poor. On examination of the abdomen there was noted slight distention of a general character with distinct fullness in the right iliac fossa. There was not, however, rigidity of the right rectus and only slight tenderness on palpation over the appendix. No mass could be felt in this region. The pain in the joints was of such a character that during the examination, when the elbow was inadvertently raised by the examiner, the patient cried out in pain. Suspecting that the abdominal pain was a secondary manifestation of the general septic infection and remembering that a high leucocyte count is at times persistent in the convalescence of scarlet fever, cathartics and high enemas were advised with the result that when seen next morning the fullness in the right iliac fossa, as well as the pain, had largely subsided, and the patient made a recovery which was complete.

so far as the abdominal condition was concerned, though she later developed cardiac complications of a most serious nature and finally died of septicemia.

There is little doubt that in this case the pain in the abdomen was due to the scarletinal infection with associated extension to the appendix and that the added strain of an operation would have speedily caused a fatal outcome.

Abdominal pain following typhoid perforation in children presents similar features to that which occurs in adults. It is acute in character and readily diagnosed, as in addition to the clinical picture of typhoid fever there are the signs of a rapidly spreading peritonitis with its attendant serious complications, a sudden drop in temperature and collapse on the part of the patient.

Empyema, abscess of the lung and sub-phrenic abscess may be complicated with extension to the peritoneal cavity. This is usually indicated by a varying degree of abdominal distention associated with comparatively little pain, except in the case of the sub-phrenic infection, which is always extremely difficult to diagnose and rather rare in children. The pain and tenderness low down near the costal border associated with a septic temperature and the presence of pus, when the exploratory needle is used, clearing up the diagnosis.

The pain of volvulus or intussusception is paroxysmal in character and in the case of the latter associated with the presence of a tumor-like mass of varying size. With volvulus we of course get the symptoms of obstruction. In addition to this in intussusception there is usually present a discharge of mucus and blood from the rectum and in the more severe cases the protrusion from the anus of a portion of the involuted gut. Difficulties in diagnosis are often experienced, as instanced in the following case:

A patient eleven years of age had complained during a full year of constantly increasing abdominal distress. Onset of the present acute attack occurred two weeks previous to the consultation. It was the most severe she had suffered from. The temperature was 103° at the time of the onset and continued for four days, when vomiting commenced. Intermittent pain was complained of throughout. Constipation was the rule from the onset of the symptoms. The patient was unable to secure a satisfactory movement of the bowels after the last attack of pain. A general physical examination did not reveal a lesion in the lungs, and the patient was in very good condition considering the difficulties of the past year through which she had passed. Examination of the urine was negative. The blood count was low. The cervical glands were not enlarged. Examination of the spine was negative. The abdominal examination presented the following picture: There was considerable distention. In the region of the umbilicus was a mass 20 cm. in diameter, which occupied the mid-abdominal region and was especially prominent above the navel. It was not especially tender on palpation. It was apparently firmly fixed. The percussion note was slightly dull. The abdominal region below the midline was somewhat tender to pressure. Palpation over the kidneys was negative. Rectal examination showed no mass or tenderness. It was finally decided to operate, but only after several days had elapsed during which every effort had been made to move the bowels by means of high enemas. The result obtained from these was simply mucus and a small amount of blood. The preoperative diagnosis was intussusception. At the operation it was found that the tumor consisted of coils of intestines firmly adherent to a mass of inflamed glands with a focus which suggested that the source of the infection might be the appendix. This, however, was not found. The

adhesions were broken up, thorough drainage of the infected area was instituted, and the patient made a successful recovery. Sections made from portions of the glands removed, which were somewhat cheesy in consistency, did not reveal the presence of tubercles, neither were the intestines studded with areas suggesting the miliary type. There was no fluid in the abdomen.

The abdominal pain associated with pyelitis in children is quite characteristic. Particularly is this true of that caused by the pyogenic infections whatever their type. A routine examination of the urine should be made in the case of any child suffering from a general infection. The importance of this cannot be over emphasized.

A young girl of 14 years seen recently illustrates this point. For several weeks she had presented symptoms suggesting typhoid fever with a somewhat typical temperature. Suddenly abdominal pain of a dull aching character developed in the region of the right kidney, with a very marked distention of the abdomen. This pain was centralized in the right lumbar region. The Widal test was negative. The differential leucocyte count was low. The patient's general condition was excellent, though she was still running an afternoon temperature, which at one time was 102°. Examination of the abdomen showed on inspection considerable distention without the appearance of a tumor-like mass. On percussion the note was distinctly tympanitic. On palpation there was tenderness localized over the right kidney. The urine was found to be filled with pus cells. The general physical examination was negative. Diagnosis pyelitis.

Pyelitis should be one of the first things thought of when the physician is called to see a sick child with somewhat obscure symptoms. Its onset is often sudden and insidious. It is associated with local pain over the affected kidney, chills and a marked rise in temperature. There is often present abdominal distention. A careful examination of the urine revealing pus cells and the caudate type characteristic of the disease are sufficient to establish the diagnosis. Acute pyelitis may exhibit exacerbations and recurrences or may develop into the chronic type with retention of pus in the pelvis of the kidney leading to pyonephrosis. Pains stimulating renal colic of a recurrent character with septic temperature are often present, relief being obtained when the pus is discharged into the bladder.

Abdominal complications and intestinal stasis suggest peritonitis. The extreme pain and tenderness on palpating the region of the kidney present the clue to the diagnosis. Care must be taken to give the patient the benefit of medical treatment in these cases, as they usually clear up and rarely require surgical intervention. Pyelitis should be constantly borne in mind in all cases developing an erratic temperature without the physical examination revealing a definite pathological process.

The possibility of lead poisoning should always be considered in the case of a child as well as in that of an adult.

The cause of abdominal pain in children is often very difficult to determine, and it is to be hoped that a review of its etiology will serve to emphasize anew this important fact. It is a symptom of the greatest importance and always points toward a diseased condition which must be carefully investigated in each case.

PHYSIOLOGY OF AEROPHAGIA.*

By S. J. MELTZER, M.D..

NEW YORK.

ON account of the many references to my own work which are contained in Dr. Kantor's paper, I shall try, in spite of the lateness of the hour, to make the following few remarks which may be of some value to those who are working in that line.

To my mind, a fundamental error crept into the conclusions drawn from the observations made in the studies by means of x-rays of the physiological movements of the gastrointestinal canal, especially those of the esophagus. In these studies the *progress and regress of the substances within the canal*, observed by means of x-rays, were erroneously taken as an expression of the *physiological movements of the corresponding part of the canal itself* which is to accomplish these movements. Soon after the first communication of Cannon and Moser, which was based on x-ray observations made on the esophagus of animals after administering a bolus containing bismuth, I made *ocular* observations of the behavior of the peristaltic movement of the esophagus when the animals swallowed a bismuth-containing bolus. I found that in not a single instance was such a bolus brought down to the cardia by a *single* act of deglutition; the peristaltic wave regularly runs its normal course while the bolus remains in some part of the esophagus, either being separated into several particles or remaining connected in an olive-shaped mass; in the latter case, the peristaltic wave, when reaching the lower part of that olive-shaped bolus, produced rather an upward movement of the latter, which in an x-ray picture would appear as an *antiperistaltic* movement. At any rate, it required a greater number of regular peristaltic waves to bring the entire mass down to the cardia and into the stomach. The x-ray picture then did not show the physiological course of the peristaltic wave of the esophagus which follows each initial act of deglutition, but presented merely the progress of the bismuth containing bolus.

I wish on this occasion to emphasize the practical and important value of the deglutition sounds which were described by me in 1883. But from a long experience I can say that not many made a proper theoretical study and practical use of these sounds. I have seen several physicians who even specialize in gastroenterology and who have never heard the so-called first sound; they confounded it with a dull, short sound which is sometimes heard immediately after the initial act of deglutition, and which is similar in character to the sound which can be heard at the back of the individual (Hamburger). From personal experience I know that Ewald was one among them; nevertheless, most of the statements in the literature are based upon Ewald's later discussion of the subject (1884). One who ever heard a characteristic so-called first sound would never forget it; it produces a sensation as if the swallowed fluid ran into one's ear. Ewald also is responsible for the terms "first" and "second" sound, which gives an erroneous impression; that is, that during every single act of deglutition there is a first and a second

sound. The so-called first sound is a rare phenomenon, and it occurs only when the tonus of the cardia is considerably reduced. In my original description of these auscultatory phenomena I designated the so-called first as a "squirting sound" and the second as a "pressing sound." I wish to emphasize that if several deglutitions follow one another within two or three seconds the press sound (second) is heard only after the last swallow, because the primary act of each deglutition causes an inhibition of the peristalsis of the esophagus. However, if a good many swallows follow one another in short order, the deglutition sound in the epigastrium makes its appearance irregularly, and often has the character of the squirting sound (first).

I would ask Dr. Kantor to be good enough, in closing the discussion, to give an exact definition of the meaning of aerophagia. In the literature I find that various writers include under that caption the accumulation of gases in the stomach and eructation, belching of gases. Now, in most instances, the accumulation of gases in the stomach has nothing to do with aerophagia; the gases may be there by some pathological conditions developed within the stomach itself, or may enter there from the duodenum through a patulous pylorus. To my mind, neither of these conditions has anything to do with that which I am inclined to understand under the term aerophagia. Aerophagia, I believe, is due to the pathological ability of voluntarily swallowing air without any food or drink, or with a mixture of very little of them. I have been interested in the physiological process of deglutition for nearly forty years, and during the time of my active practice I saw a good many patients, but I have to confess that I never saw a case which I would have designated as aerophagia. This does not prove that such a pathological phenomenon does not exist, but it is probably a very infrequent phenomenon. I have formed a conception of the physiological nature of the etiology of aerophagia, and I shall try to state it here very briefly. The pharynx when at rest contains a small quantity of air. The deglutition is initiated by raising the larynx and the posterior, fleshy part of the tongue, which then reflexly is suddenly pressed into the pharynx, working like a piston, thus sending the contents of the pharynx into the esophagus, which becomes relaxed by means of the accompanying inhibitory impulse. The following peristaltic wave sweeps down anything present in the esophagus into the stomach, thus bringing there a small quantity of air. When the swallowing is "empty," the amount of air is, of course, larger than when any food or liquid is swallowed. Normal individuals are capable of accomplishing "empty" swallows not more than four times in succession. The quantity of air in the stomach is, under these circumstances, larger than after swallowing food or drink. A part of this air escapes backward, without producing any noise. But, as I found some years ago, even this slight eructation is followed by that which I have described as *secondary peristalsis*; that is, a peristalsis of the esophagus without being preceded by the initial act of deglutition. There are individuals who are capable of accomplishing a larger number of "empty" swallows in succession. This, of course, may produce a considerable distention of the cardiac part of the stom-

*Remarks made at a meeting of the Section on Medicine of the New York Academy of Medicine, December, 1917, in the discussion of Dr. Kantor's paper.

ach, which in turn may rather increase the tonicity of the cardia and thus prevent the ready escape of the air from the stomach. The ability of accomplishing many "empty" swallows in succession is probably based upon the lowered reflex threshold of these individuals. In some instances the lowering of the reflex threshold is peculiar to many functions of the body of these individuals; we may designate them as hysterical. In other persons the lowering of the threshold is, for some reason or another, confined to the reflex of deglutition. In short, *Aerophagia is produced by a succession of "empty" swallows in individuals whose threshold for deglutition reflexes is abnormally low.*

13 WEST 121ST STREET.

A STUDY OF HISTORY AND SYMPTOMS AS BEING OF MORE VALUE TO THE GENERAL PRACTITIONER THAN PHYSICAL AND LABORATORY FINDINGS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

BY S. A. SLATER, A.B., M.D.,

OIL CITY, PENN.

SUPERINTENDENT GRAND VIEW SANATORIUM.

THE general practitioner will always be a most important factor in the fight against tuberculosis. He is the one who first sees the patient and has the opportunity to make an early diagnosis. He is the one the patient has probably known for many years and in whom he has the utmost confidence. He is the one whose advice and counsel a patient will follow quicker than that of any one else. He is the one who holds the power to direct the patient at a time when advice and proper instruction may save him. All this, however, will go for naught unless he is able to make a diagnosis of tuberculosis when the chances for recovery are good and before the disease has become so far advanced that the patient is a source of danger to those with whom he associates.

Any one doing tuberculosis work will tell you the most important thing for the good of the patient and the safety of others is an early diagnosis. This not only gives the patient a chance to recover, but he can be taught to take precautions before he has become a source of danger. Rightly may the general practitioner say, "Why, most of these cases are well advanced before they consult us." I am willing to give the patient the blame that is due him and know there are many who harbor well advanced disease before ever consulting a physician. On the other hand, there are many who see the physician in the earlier stages, but without a diagnosis. In taking the histories of a large number of patients, as is done in sanatoria, one cannot help being impressed at the time the patient has suffered from the disease and the number of physicians consulted before a diagnosis is made. They often give a history of having consulted four or five physicians, even when presenting such symptoms as blood spitting, digestive disturbances and severe cough without getting a diagnosis. Unfortunately for the profession, these patients never blame them-

*Read before the Oil City Medical Club, Oil City, Penn., October 11, 1917.

selves for the failure of diagnosis. The same patient who will discharge the first physician who tells him the trouble and hold to the one who tells him he is "as sound as a dollar" will knock all the physicians who have seen him and blame them for not making an early diagnosis, when the real nature of the disease is known and the patient has reached the incurable stage. Although hopeless as far as complete recovery is concerned, they often live a long time and can do a lot of knocking, which sometimes makes it uncomfortable for the physician. It is to the advantage of the physician to make a diagnosis as early as possible and when he has done so to tell the patient the exact condition. The importance of informing the patient as soon as a diagnosis has been made cannot be over emphasized. No physician can get results in treatment or the cooperation of patient in carrying out instructions and taking precautions unless he first convinces him he has the trouble and impresses upon him the seriousness of the situation. The idea of a physician saying "I can't tell the patient, for I feel that he will give up as soon as he knows his condition," is absurd. I have yet to see the patient who died because of being told he had tuberculosis, but on the contrary it is the only way to get his cooperation. The physician who fails to tell the patient cannot be condemned too strongly and should be made to live with open cases of tuberculosis, as he is having the patient's family do, until he is thoroughly impressed with the importance of having him take the proper precautions.

You have seen the importance of an early diagnosis not only for the benefit of patient and family but for that of the physician himself. Now how best can a diagnosis be made? If I had to depend on only a part of the means at hand in making a diagnosis and could choose those I prefer in their relative importance, I would take first the history of the patient, second the symptoms, third physical signs, and fourth laboratory findings. Apparently this is just the reverse of the views held by the general practitioner. Only too often he feels he has done his duty when he has gotten a specimen of "something" the patient expectorates, it matters not whether it comes from mouth, throat, nose or lungs, and sent it to the laboratory to be examined. If the report comes back negative he does not have tuberculosis, and very likely another specimen is not sent. He does not stop to think of the many things that might prevent the finding of germs although they may be present. The finding of germs is absolute proof of the disease; if they are not found it is no proof of itself that the disease is not present. Only about one-third of the incipient cases of the larger sanatoria, where most careful sputum examinations are made, show bacilli in their sputum at any time. Are you going to wait for the patient to pass the incipient and curable stage of the disease only to find the germs?

The chest examination is practically worthless in itself. The more expert the examiner the less apt he would be to rely on this alone. This, together with other means at the physician's disposal, becomes of great importance, especially when carefully done by one experienced in a study of chest conditions. As stated above, the most important things we have at our command are a carefully

taken history and a study of the symptoms; these alone when properly taken will give us sufficient information to arouse our suspicion when tuberculosis is present, and if it is not possible to make an absolute diagnosis it will give an opportunity to refer the patient to one who can, and before it is too late.

The history which is of the greatest importance in the study and diagnosis of any disease can be obtained by all physicians, although some may be decidedly more expert than others. Anything so valuable to a physician should be carefully studied and used to the fullest extent. History taking is an art in itself and one well worth cultivating.

The symptoms likewise can be obtained by all physicians who will take a little time to ask questions and listen to the patient's answers. These are of secondary importance only to the history in the hands of the general practitioner and should be studied in every case, whether tuberculosis or measles. Obtaining either history or symptoms is comparatively simple for the physician, since it should be their routine practice with every patient which consults them.

A chest examination is different and would naturally fall to one who confines his study to this line of work. It takes experience and constant practice to be efficient in interpreting the earlier changes in the lungs. The medical colleges of ten years ago gave a very limited course in physical diagnosis and practically nothing which would be of value in detecting incipient tuberculosis. Many physicians are graduated even to-day who have never had an opportunity to study an incipient case. It is, therefore, not to the discredit of the general practitioner not to be able to detect early tuberculosis by means of physical findings. It would be decidedly more to his discredit to rely on this method and neglect what is more important, the history and symptoms of the patient.

The expert would not think of making a diagnosis on physical findings, but would use these only with all other means available, if the case was at all an early one and required any skill in ascertaining the nature of the disease. The purpose of this paper then is to bring out the importance of the study of the history and symptoms of patient in the diagnosis as being of greater value to the general practitioner than physical signs and laboratory report in the diagnosis of tuberculosis.

In proof of the above statement I will say that some of the earliest cases I see are those referred by physicians who have never made a chest examination of the patient, but by a study of history and symptoms felt that tuberculosis was present.

History.—Nothing is of more importance than a carefully taken history; it should go into the most minute details and nothing should be taken for granted. The family history is carefully taken, not on account of the old idea that tuberculosis is hereditary, but to find out if there has been any intimate exposure. To ask if any relative has ever died of tuberculosis is not sufficient. Begin with grandparents and study each individually, learn the cause of death in each instance. If the nature of the disease cannot be ascertained, endeavor to learn if they had a chronic cough, suffered from asthma, bronchitis or a run-down condition; if any

of the family died of a disease simulating in any way tuberculosis; ascertain if the patient was intimately associated with said member. It is important to learn all about the grandparents and whether any of them living in the home of the patient ever had chronic bronchitis or other chronic conditions resembling in any way tuberculosis. A great many of these dear old souls suffering with what is considered chronic bronchitis have chronic tuberculosis, and although they may have reached an advanced age before death they are among the most frequent causes of infection in the grandchildren. I want to emphasize the fact that these so-called cases of chronic bronchitis are our most fruitful sources of infection, for many of them are open cases of tuberculosis which seem apparently healthy with the exception of a slight "bronchial trouble." If any member of the family has died of tuberculosis it is important to know whether patient was intimately associated with the victim during the time when the disease was active. It is also well to find out age of patient at time of exposure. Children are very much more susceptible than adults, and it must not be forgotten that although a child may be infected during early life he does not necessarily show symptoms until he becomes an adult, and many infected in childhood never show any signs of the disease.

Having carefully studied the family history the next is to get that of the patient. The first is to learn what the home conditions were from earliest childhood, then a study of the childhood diseases; only measles and whooping cough are of importance, and the patient should be most carefully questioned regarding his health following either of these, especially if he did not contract them until adult life. Learn what you can of the patient's general health, ascertain whether he had any glandular involvement during early life, ever suffered from pleurisy, fistula in ano, ischio rectal abscess or discharging ears; these are often forerunners of active pulmonary tuberculosis. Ascertain what diseases the patient has had, such as frequent colds, grippe, pneumonia, typhoid fever, or any injuries of the chest, also if he made an uneventful recovery. It must be remembered that any condition which lowers patient's resistance predisposes to tuberculosis, and one should be suspicious of typhoid, pneumonia or other disease when the patient is slow recovering.

Habit and occupation of patient should be carefully gone into. It is more important to find out the condition under which the patient works and lives rather than what he does. It is much safer for one doing a work considered predisposing to tuberculosis and live under the best conditions than it is to do something considered safe and live an irregular life in unfavorable surroundings. One's habits are worthy of careful consideration. Learn if possible whether patient leads a regular life, smokes, chews, drinks or indulges in other dissipation to excess. The past history of patient being carefully considered, his present illness should be fully studied. Ask him how long it has been since he felt perfectly well rather than how long he has been sick; go back to the beginning and find out all that is possible between that time and the time patient consults you. It is often necessary to go over certain parts and help the patient to remember

how his symptoms developed. It requires skill and patience to bring out a complete and valuable history.

Having obtained a full history of the patient, the next step of importance is to study each symptom or to find out just what symptoms the patient has developed.

In a study of the symptoms of tuberculosis it will be necessary for the physician to turn the old Hippocratic picture, emaciation, cough, night sweats and high temperature, to the wall and study the earlier symptoms if he is to make an early diagnosis. There is no pathognomic symptom of tuberculosis; what one patient will complain of first and most constantly the next patient will never have. Tuberculosis, like syphilis, can run the most obscure symptoms, and these two diseases should always be kept in mind when considering a disease of obscure nature, since they are among the commonest, yet often the last to be thought of in making a diagnosis. For a study of the symptoms I will group them according to Pottenger¹ under three headings:

Group 1 Toxemia	Group 2 Reflex Origin	Group 3 Tuberculous Involvement per se
Malaise	Hoarseness	Frequent and Protracted Colds
Lack of Endurance	Tickling in Larynx	Spitting of Blood
Loss of Strength	Cough	Pleurisy
Nervous Instability	Digestive Disturbances	Sputum
Lack of Appetite	Loss of Weight	Fever
Digestive Disturbances	Circulatory Disturbances	
Loss of Weight	Chest and Shoulder Pains	
Rapid Pulse	Flushing of Face	
Night Sweats	Apparent Anemia	
Fever		
Anemia		

Some of these symptoms fall in two groups. Those of group 1 may all be due to some other cause than tuberculosis and must be studied with symptoms of groups 2 and 3; on the contrary, active tuberculosis may be present without any of the symptoms of this group.

The first symptoms of the group, malaise, feeling of being run down, lack of endurance and loss of strength are very common and are often the symptoms which first brings patient to physician. The patient does not seem to have the usual amount of energy, does not take the usual interest in things he formerly did. This is a very suspicious symptom and especially if the patient states that he feels as tired or more so after a night's sleep than before retiring. Nervous instability is a condition often diagnosed as neurasthenia. This is only the giving of a name for a symptom which in a vast majority of cases is due to tuberculosis. The physician should not be satisfied until a satisfactory cause rather than a name is found for this condition.

Digestive disturbances are common in tuberculosis; often the food is not properly digested. Again the patient complains of loss of appetite. He often feels hungry until food is placed before him, then all desire for it disappears. This is especially true when the patient is tired. I make it a rule to notice a patient's appetite very closely when first placing him on exercise; if it declines one can be quite sure patient is doing too much. Tuberculous patients often have a good appetite, however, when running quite a high temperature, which is of value in differentiating it from other diseases when the patient has no appe-

tite with a high temperature. I have seen a number of cases treated for stomach trouble a year or longer when the real cause was tuberculosis, when a diagnosis was made and patient treated accordingly an improvement was noted.

Loss of weight is frequently met with in tuberculosis, and many physicians seem to think a patient has to be greatly emaciated before he can have the disease. While it is well to investigate the condition of patient's weight, on the other hand it must not be forgotten that a patient can look fleshy and not lose any weight and still have tuberculosis. One should ascertain the patient's greatest weight, present weight and estimated normal weight, for often one weighs himself too infrequently to tell whether he has lost recently. On the contrary, a person sometimes notices he is steadily losing weight and consults a physician on this account; when this is the case the cause should be ascertained if possible, for it is too often tuberculosis. When the disease is suspected the patient should be weighed once a week.

An increased pulse rate is considered by some a most important symptom. Certainly a pulse higher than normal without a definite reason for same should be looked upon with suspicion. A case of tuberculosis running a high pulse and practically normal temperature has a rather unfavorable prognosis.

Night sweat is often the first symptom which causes a patient to consult a physician, and it is one of the symptoms looked upon by the laity as proof of tuberculosis. The sweats are due to a toxemia which may be produced by other conditions than tuberculosis; still it should always be looked upon with suspicion until the real cause is ascertained. The physician should not wait until the advent of night sweats to make a diagnosis, for it is a sign of extreme toxemia and advanced disease when present in tuberculosis.

A careful study of a patient's temperature is most important. To take a temperature once a day or when patient calls at office is decidedly worse than not taking it at all. A temperature to be of any value should be taken every two hours for one week, and no matter what kind of thermometer is used it should remain in the mouth for at least five minutes. Only too often have I had patient's temperature reported by a conscientious physician as being below 100° only to find on arrival at the sanatorium he is running a temperature of 102° or higher. This was not because the physician wished to report an incorrect temperature, but because it was taken under the wrong conditions or the thermometer was not allowed to remain in the mouth long enough to register. Do not look for a high temperature in an early case; an afternoon temperature of 99.5° which cannot be explained should cause one to be suspicious of tuberculosis. A temperature decidedly subnormal in the morning is of equal significance and calls for a careful study and explanation.

Symptoms of Group 2.—As you will notice, the symptoms of this group direct one's attention to other parts than the lungs. Some of these, digestive disturbances, loss of weight and circulatory changes, have been discussed under group 1 and will not be taken up again.

Hoarseness is one of the most common early symptoms and one of the most neglected. This condition is too often treated, even by the throat specialist, without even thinking that it might possibly be due to tuberculosis. This is a most frequent symptom and should always be looked for when there is any suspicion of the disease. It is especially apt to be noticed when the patient is slightly tired or after talking or singing when the voice has been strained. It may be due to several causes; first and most common in early tuberculosis is the failure of patient to approximate cords on account of reflex nervous condition. Again mucus may become attached to the cords, which prevents their free movement, and, lastly, the larynx may be the seat of a tuberculous process. Do not think from this that the disease starts in the larynx, for such is not the case.

The cough is another most common symptom; in fact, there are extremely few, if any, patients who have the disease and do not cough. Often a patient denies having one, but if carefully questioned he will admit that he has a slight hacking cough, most probably the first thing in the morning. This will often be noticed first by some member of the family. This morning cough, with or without expectoration, should lead one to think of tuberculosis. Any cough lasting more than two or three weeks should arouse suspicion and calls for a careful study of the case. The patient will often try to explain that it is due to a tickling in the throat, a little bronchial or catarrhal trouble. The so-called emetic cough is also a common symptom and when present should be most valuable in confirming a diagnosis. The patient will cough after a meal and vomit, although he does not have any sick feeling or discomfort of the stomach; when it is present the physician can be reasonably sure it is due to tuberculosis.

Chest and shoulder pains are often complained of by patients. They are as common in pulmonary tuberculosis as rigidity of rectus muscle is in appendicitis and should always be looked for in suspicious cases. Often the patient complains of them thinking he is suffering from rheumatism; or he will complain of feeling tired across shoulders. This calls for a most careful study of the case and will often reveal tuberculosis. He may also complain of a chilly sensation, which is most common along the spine, or he may notice he is more susceptible to changes in the weather than usual.

Flushing of the face is quite common, but is more often indicative of advanced or very active disease than a symptom of the early stage. The patient complains of one or both sides of the face feeling hot and flushed. When the process is confined to one lung the flushing occurs on that side, when present in both lungs it is noticeable on side in which the lung is more extensively or actively involved.

Menstrual irregularities are very common in young girls and women suffering with tuberculosis. One patient will complain of the flow being excessive and occurring at too frequent intervals, while the next will complain that the flow is diminished, occurs too infrequently or not at all. The real cause of such condition should be sought and not explained as being due to chlorosis, anemia or a run-down condition, as is too frequently the case.

As you see, most of the symptoms described above can be caused by other conditions than tuberculosis; still when carefully studied with those of group 3, which I now describe, will be of great value in making a diagnosis.

The symptoms of group 3 are due to the lung process *per se*. The first of these, frequent and protracted colds, are often encountered. The patient complains of contracting one cold after another; he may complain of having a cold which lasts him practically the whole winter. Most of these patients are suffering from tuberculous bronchitis. If these colds are severe they are called grippe, and sometimes they are diagnosed as pneumonia. Recently a patient in the far advanced stage of tuberculosis was admitted to the sanatorium giving a history of having had at least three attacks of pneumonia during the past winter. These were only exacerbations of an active tuberculosis. Symptoms such as the above always call for a close study of the patient, for they are due to tuberculosis more often than otherwise.

Blood-spitting is a symptom which will usually cause a patient to make his own diagnosis. Still physicians seek to find other causes for it and give an erroneous explanation to the patient only to lull him into a feeling of false security. If any symptom is pathognomic of tuberculosis, it is the spitting of blood. There are causes other than tuberculosis which provoke blood-spitting, but they are so rare that it should always be looked upon as being due to this cause until proven conclusively otherwise. It seems absurd to think of a physician offering other reasons for the spitting of blood until a patient has passed beyond the stage when treatment will be of any value. A patient once came under my observation after being referred by his family physician to a throat specialist, who, upon examining the throat, stated he could see the bleeding point. A few days later the patient had another hemorrhage, and again consulted the family physician, who assured him he need have no worry, and it was not until he had a large hemorrhage in the presence of the physician that the correct diagnosis was made, and that only a few months before his death. Many other cases could be mentioned in which a misinterpretation of common and definite symptoms has led to as disastrous an ending. If in every case of frank hemorrhage an immediate diagnosis of tuberculosis was made and the patient treated accordingly there would be decidedly fewer mistakes and many lives saved. To give a patient who spits blood an erroneous excuse for its appearance is an exposition of ignorance on part of the physician. Hemorrhage cases offer a fairly good prognosis if given the proper treatment early; any one spitting blood should be immediately given the advantage of the doubt and treated as though he had tuberculosis until it is proved otherwise.

Pleurisy also holds a more important place in the diagnosis than is usually given it. The vast majority of pleurisies are tuberculous and should be treated as such. Pleurisy is always serious and should be so taken. The general practitioner would be surprised if he were to look up the cases of pleurisy he treated from ten to fifteen years ago which apparently made a good recovery, for he would find that at least half had since died of tuberculosis. In taking the history,

then, ascertain if the patient has ever had pleurisy; if such is the case, your diagnosis is reasonably sure. A history of previously having had pleurisy is second only to that of blood-spitting, and when either of these has been present in the past the physician need not have any great fear of making a diagnosis of tuberculosis; certainly when there are other symptoms which will help confirm it.

If the general practitioner will put more importance in the history and symptoms of cases of tuberculosis presenting themselves for treatment, an early diagnosis will be made more frequently. As shown above, there is no one symptom pathognomonic of the disease, but when all the symptoms are taken together with the history of patient, most valuable evidence will be obtained toward a diagnosis. A physical examination alone is of less value, and a diagnosis cannot be made by means of it. A patient does not always require treatment when presenting physical signs of the disease. Brown² says "Physical signs tell by inference what has happened in the lungs, symptoms what is happening." A careful study of symptoms is not only valuable in aiding in diagnosis, but is valuable in determining what should be done with patient.

In the future let me urge you as physicians to place more importance in a study of the history and symptoms in order to make an earlier diagnosis of the disease and be better able to render a greater service. If the fight against the Great White Plague is ever to be a success, it will have to depend on an early diagnosis of the disease by the general practitioner. Your greatest efforts are needed not only for the benefit of your patients but that this dreadful disease may be successfully fought and finally wiped out.

THE UNSETTLED QUESTION AS TO SCURVY BEING PRODUCED BY FEEDING PASTEURIZED MILK.

By J. M. W. KITCHEN, M.D., M.S.
EAST ORANGE, N. J.

THIS question can be answered by either yes or no. I believe that, as far as direct effect of heating on the nutritive constituents of milk is concerned, this influence will not cause the disease. I do not believe that if pasteurization is properly performed the enzymes or the vitamins are destroyed to any extent that is not negligible. Note that I say "properly performed," for there are both poor and ineffective heating methods applied in pasteurization. Very high heat contact with milk will have a damaging effect in destroying some of the food constituents, and in hardening albumins.

I believe that in so-called infantile scurvy-like conditions there are always coincident, predisposing conditions present inducing a scorbutic diathesis, that are other than the influence of pasteurized milk, including conditions in the milk due to accumulations in it of putrefactive fermentative products.

I am not a pediatricist, but believe in safeguarding all milk through its heating. I have no prejudices

for or against the view held by so many, that the feeding of pasteurized milk produces scurvy in infants. That scorbutus-like symptoms may occasionally occur in infants who have been fed pasteurized milk is admitted; but it is not proven that heating the milk produces these symptoms; and inasmuch as there is still existing a very widespread lack of acquired information of specific knowledge relating to the milk question, it may be permitted for the student to doubt as to the soundness of the conclusions of some pediatricists as to the matter. Certainly the question is still *subjudice*. The symptoms that may occur once in a while in a baby fed on pasteurized milk may be and probably are induced by some coincident cause or combination of causative influences.

The evidence in hand indicates that the mere moderate heating of the milk is not the cause of those symptoms. It is even questionable if a sterilizing heat of itself alone is a productive cause of such symptoms.

Every item of information relating to this question that has been obtainable by me has been read and studied, and frequently reread and restudied. In particular, I have been rereading the Transactions of the American Pediatric Society, and those of the American Association of Certified Milk Commissions for the year 1916. At the 1916 annual meeting of the Associated Milk Commissions it was admitted by many that there had been a widespread incidence of bovine tuberculosis in certified herds. A prominent and intelligent dealer in my home community has told me that he does not believe that there is any herd in the United States that is entirely free from this scourge. In view of my own disastrous experience in connection with my carefully protected herd, I am inclined to his belief. If it is true that over 90 per cent. of children show signs of having been tuberculously infected, and that over 50 per cent. of the herds in this country are badly infected, what possible good excuse is there for not safeguarding *all* milk by sufficiently heating it, or otherwise treating it so that entire assurance is attained that, at least, complete destruction of all pathogenic germs has occurred.

As yet I have not come upon evidence that convinces me that a properly conducted pasteurization damages milk sufficiently to warrant the withholding of that protective measure.

My reasons for holding that view are as follows: The evidence in hand indicates the formation of and accumulation in milk of toxic fermentative products as being, through direct and indirect constitutional effects, more inducive of scorbutic manifestations in bottle-fed babies than heating.

All grades of milk, including the most carefully produced of "certified grades," have been more or less infected and contaminated during production, and have undergone more or less fermentative changes at the temperatures maintained in the usual methods of handling milk, both before and after pasteurization. Such contaminations may have a considerable predisposing effect on babies.

The only reason I can see why the high heating of milk could damage it for feeding purposes is the indirect effect due to the pasteurizing heat that usually destroys 95 per cent. or more of the milk bacteria, most of which are of the inert and lactic

acid forming types; and hence, when the milk is ingested, there may not be so much stimulative effect on the alimentary tract from acid fermentative action therein, for the acid produced in raw milk may help the alimentary acids in the digestion of the milk, as well as incite vigorous intestinal activities. That such theory is of value is backed by the fact that so many of the milk bacteria are of the acid-forming types, and that the most useful antiscorbutic agents are more or less decidedly acid in character, such for example as vinegar.

In view of our lack of definite information as to the enzymes and the so-called vitamins, one should not be too positive in expressing an opinion in this connection. However, it is extremely improbable that scurvy is a disease due to the nonpresence of enzymes in food, or to the coagulation of food albumins. It is even very questionable if the possible absence of vitamins in milk is the cause. A boiling heat does not destroy the vitamin principle or nutritive element in other alimentary substances; and there is no evidence that heat destroys that principle in milk—even sterilizing heat—although artificial heat probably decomposes milk more or less in proportion to its intensity of influence. Scurvy must be a very rare disease in babies who have been fed even on boiled milk, for thousands of babies so fed in Europe have been treated in European clinics without any case of scurvy having appeared.

It was definitely and generally agreed long ago that scurvy is a dietetic disorder superinduced, at least, by a lack of some food principle abundantly furnished in lemons, oranges, potatoes, pickles, cabbages, apples, and other fruits, and in various other plant products. Apparently the more acids that are present in such products, the better they act as antiscorbutics. If the potassa in such antiscorbutics is the potent principle, heating milk would not eliminate that element. We should admit that while even moderate heating may destroy the enzymes, yet that destruction may not cause scurvy. The anatomical changes in scurvy indicate a generally defective nutritive activity in the individual, while the existence of acids in the dietetic remedies for the scorbutic symptoms indicates a possible helpfulness from those acids and their possible stimulative alimentary effect. Inasmuch as the undestroyed bacteria in raw milk are largely acid formers, if the milk seeded by those bacteria would induce a fermentative production of acids in the alimentary canal, it seems reasonable to think that the acids in orange juice, or in other antiscorbutics, would be effective substitutes for acids developed in raw milk that has been seeded with such acid-forming germs.

If the disordered, scurvy-like condition seen in babies, and which, so far as I know, is only infrequently seen, is like the conditions seen in old times in soldiers and sailors, then the direct causation of the anatomical changes seen in infants has in all probability been at least partly resident in defective general nutritive conditions, or in alimentary functional defects, rather than in defective digestibility in the food consumed. I do not know that anyone has claimed that the enzymes directly furnish constructive nutrients. Presumably they merely act by their presence in aiding digestion. But even

if they are destroyed by heat, their elimination can be readily made good by the various modifications in and additions to the milk fed.

It is not unreasonable to believe that the addition of fruit juices to the milk may enhance the individual's activities in the alimentary tract, and which would not occur if the 95 per cent of more of bacteria in the milk fed had been destroyed by heat. It is conceivable that elimination of bacterial activity in the milk may result in more or less intestinal stasis, with consequent defective intestinal elimination of effete ferment products, and their constitutional absorption and diffusion. It should be remembered that some of such products may have accumulated in the milk before its ingestion by the infant. As a matter of fact, more or less accumulation of such toxic matters always occurs in milk under the present day and previously practised methods of producing and handling milk. "Certified milk" should be credited with a lesser accumulation of such excretory matters, but not complete exemption from such accumulations.

It was a widespread belief and practice in the days prior to the advent of bacteriology, that boiling milk exerted an anti-dysenteric influence. This fact adds weight to the present contention that destruction of bacteria in milk may induce static alimentary disorders. If that theory is correct, then we can say that pasteurization has indirectly a bad effect on milk, though an effect not worth while evading in view of the various possible counteractive procedures that can be readily applied.

No satisfactory reason has been advanced in explanation of the undoubted fact that boiling orange juice and potatoes does not destroy the antiscorbutic principles in them; and if it does not, there seems to be no good reason to think that the mere moderate heat of an intelligently applied pasteurization would destroy any essential nutritive element in the milk. Inasmuch as the acids correct any objectionable tendency to scurvy, any coagulative effect in the milk from heat would not be the cause of the scurvy.

In this connection it is interesting to note the similarity of the symptoms observable in unquestionable scurvy, and those resulting from the poisons due to the fermentative decompositions of animal proteins.

Many of the symptoms produced by bad milk are similar to symptoms produced by scurvy-inducing dietetic conditions, including the depressing and other predisposing causes that are adjuvant to dietetic causes.

It is so satisfactory to have a sound theory upon which to base one's practice that it is well to struggle to secure truth in theory. But anyway, it is clear that in view of the efficiency of antiscorbutic treatment, one ought to be very slow in subjecting a delicate infant to the dangers of possible pathogenic infections in the milk it consumes, whether to bolster up the obsolete ideal that cleanliness in production alone is a sufficient assurance of safety and wholesomeness in babies' milk, or for any other reason. There is no substitute step for the greatest possible care in preventing infections in babies' milk, though it is possible through absolute prevention of fermentations, to accept milk that has been long held, to possess the quality of freshness

of production. It should not be forgotten that late advances in methods of pasteurization secure results not accomplished by the older methods.

In considering this subject, one should refer to the possibility of pasteurization setting free in milk animal protein poisons that may exist in the destroyed bacteria. It is believed by many students that there are toxic matters in both non-pathogenic and pathogenic bacteria. If it is true that various disease symptoms are directly produced in the body by the destruction of invading and proliferated bacteria and the diffusion of the poison in the bacteria throughout the body, and that some of such poisons are eliminated through the intestines, then in theory at least, the destruction of bacteria in dirty milk may have some influence in producing infantile scurvy.

The opinion is advanced by Prof. V. S. Vaughan and others that the disastrous effect of some of the infectious diseases, such as in typhoid and diphtheria, observed in individuals of very vigorous constitution may follow a too abundant setting free of poisons at one time, due to too vigorous combat of the disease producers by the protective bodily influences. This opinion seems to be well based on experimentations which have demonstrated that relatively small amounts of the poisons in pathogenic and non-pathogenic bacteria are lethal for the lower animals, and that the greatest care must be exercised by those engaged in producing and handling those poisons.

It seems probable that the fever and other symptoms which appear after a few days of incubation following infection are due to the spread in the body of either the poisons in destroying bacteria or of excretions from the live bacteria, that are formed in the process of their proliferative growth; and that the accumulation of those products finally results in the death of the disease causative bacteria themselves.

The theory that the coincident destruction of a large number of bacteria in milk through pasteurization may add a very potent content of poisons to the milk may be worthy of consideration; although it appears defective as a theory, because orange juice and the other antiscorbutics counteract such poisonous contaminations, though we may consider that some constituent in the antiscorbutics may chemically neutralize the poisons that may have been liberated in the milk. There remains no question that very virulent poisons may be formed through fermentative action in milk, and that such poisons exert a long-time influence in those poisoned by these toxic principles.

In view of the existence of all these possibilities, it becomes all the more important that infections of any degree and proliferated infections should be prevented in milk that is to be fed to infants. These immature individuals at least have not had their bodily cells trained to combat and overcome the influences of invading bacterial enemies. Certainly, no animal or vegetable poisons, or bacteria producing these poisons, should be fed to babies; nor should adults be knowingly allowed to consume them in seriously damaging amounts. Of course, adults can withstand a considerable amount of poisoning from various sources, but that performance should not be encouraged.

In considering this branch of the subject, we should remember that bacterial influence destroyed millions of infants before pasteurization was practised; and furthermore, that billions of quarts of highly infected, pasteurized, and even boiled, milk have been consumed without any resulting symptoms of a scorbutic nature having appeared.

The accumulated evidence all goes to indicate that the direct, immediate cause of much of the infantile mortality of the past has been split protein excretory poisons developed and accumulated in milk, and has not been the direct attack of bacteria on the bodily tissues.

There is no evidence in hand to show that pasteurization eliminates accumulated poisons in milk; but if pasteurization is practised *before* the milk has lost its self-protective character, the formation of those poisons will have been prevented if no temperature influence favorable to the proliferation of the undestroyed residue of bacteria is permitted in the after handling of the milk. If a reasonable cleanliness of production is practised and pasteurization is efficiently performed immediately after production, there can be so little accumulation of poisons from destroyed bacteria that the amount would be negligible. Certainly that accumulation would be very much less of an evil than the seeding of the infant's body with the living bacteria, which bacteria might develop into millions of questionable bacteria. It has not been shown that heating milk of any bacterial character damages that milk for feeding to any degree that is not negligible. If the milk that is fed to infants is only clean and free from ferment products, it is questionable if there would be any cause of complaint due to heating in its pasteurization, especially in view of what intelligent modification can do in preparing it as a babies' food.

One of the greatest obstacles in the way of securing a satisfactory public milk supply is the prejudice that exists in the minds of many consumers that pasteurization has a damaging influence upon milk; and this prejudice is largely maintained by the opinion held by numerous physicians to the same effect. One cannot have everything in this world; and in our large cities, at least, milk that is absolutely safe, that is entirely wholesome, and that can be sold at prices that most consumers feel willing to pay, is one of the things that cannot be had. Still, all these advantageous characters in milk can be secured at a cost of not more than one cent a quart above the cost of the poorest grade B product.

In considering this subject there should be added the thought engendered by the results of the experiments of Dr. E. V. McCullum of the Johns Hopkins University in connection with the effects of foods on the growth and health of animals. Those experiments demonstrate that in most foods, though in different proportions, there are some unnamed constituents the presence of which are essential to the usual growth in animals. It is suggested that these are the so-called amino acids, which are among the multitude of cleavage products of digested proteins. Those products which are of lesser nutritive value, according to Osborn and Mendel of the Connecticut Experiment Station, are deficient in one special amino acid product which they have called

lysin, and which product is abundant in milk casein and albumin. It is theoretically possible that a heating of milk which would prevent active fermentation and consequent splitting of the milk proteins might more or less prevent a formation of the beneficent lysin and consequently deprive a growing child of an efficient acid, as well as an acid that would stimulate gastric activity. But here again we are met by the fact that the acid and other juices of the orange and other comestibles appear to make good any deficiency due to a non-fermentative production in cow's milk. It is to be deplored that later-day civilization is making of many mothers poor nurses for their children. The fact is patent that cow's milk is a defective substitute for mother's milk and should be considerably modified in one or another way before it is fed to a delicate baby. There does not appear to be any conceivable change in cow's milk that heat would effect, that cannot be counterbalanced or made good by modification and yet eliminate the danger from possible pathogenic infection. There are a good many medical practitioners, however, who would testify that they have never had a case of infantile scurvy following the feeding of cow's milk modified by barley or oatmeal gruels. Certainly the heating of these gruels does not destroy the lysin or other vitamine product character of those foods. Nor does pasteurization of milk destroy it as a first-class nutritive medium for pure and impure culture infections.

The problems relating to nutrition are only beginning to be solved. All the constituents needed in infantile nutrition are unquestionably present in mother's milk. When a child becomes old enough to digest vegetables and other foods besides milk, we can be sure that all the essential constituents for growth are supplied. In fact, all the needed constituents can be added to milk in watery solutions of the unknown growth substances found in many foods. So there is no need of worrying over the possibility that heating milk will destroy its food value, so long as its modification will secure ease of digestion. Possibly the addition of a modified gruel *before* the heating of milk may be of digestive advantage.

94 PROSPECT STREET.

Medicolegal Notes.

No Liability for Negligence of Independent Substitute.—In an action against a physician and surgeon for damages on account of injuries resulting from improper treatment following a surgical operation performed by the defendant, it was not claimed that there was any unskillfulness or negligence in the performance of the operation; but the contention was that the injury resulted from inattention or unskillfulness on the part of another physician left in charge of the patient by the defendant after the operation was complete. The patient was afflicted in a way that required a surgical operation involving an incision and entrance into the abdominal cavity. The defendant was summoned from Lake Village, Ark., to Little Rock to perform the operation, which was successfully done at a hospital there. In finishing up the operation it became necessary to leave a piece or pieces of gauze in the wound for draining purposes, and this was done. After the operation had been completed, the defendant announced that he would have to return to his home at Lake Village, and he arranged with a young physician, who was acting as interne in the hospital, to look after the patient until she recovered, and the plaintiff's case was based on the theory that the interne was guilty of

negligence in failing to remove the gauze at the proper time, and that the defendant was liable in damages because of such negligence. There was no agreement that the defendant was to pay the interne anything for his services; the latter merely agreed to the defendant's request to take care of the patient. The defendant left Little Rock shortly after the operation was completed, and did not see the patient any more; and there was no testimony tending to show that he was guilty of any negligence in the selection of the interne as a proper person to look after the patient and remove the gauze. The interne was a physician who had been selected by the hospital management to attend patients in the hospital, and there was nothing to indicate that he was lacking in qualification for the position.

The question in the case was whether or not a physician is liable in damages on account of negligence of another physician who takes charge of a patient at his request. This question seems to have been settled against the right to recover under those circumstances in a decision of the same court (the Arkansas Supreme Court) in the case of *Keller v. Lewis*, 65 Ark. 578, 47 S. W. 755. The facts of that case were that the son of the plaintiff sustained a dislocation of one of the joints in his arm, and was taken to Dr. Keller, the defendant, for treatment. Keller was about to leave the city, but gave the dislocated arm temporary treatment, and recommended that the patient be taken to another physician, with whom Dr. Keller had arranged to look after his patients in his absence. One of the theories in the case was that the other physician was guilty of negligence in failing to treat the dislocated joint at the proper time, and the defendant asked the court to give an instruction to the jury that the defendant could not be held liable for the negligence or want of skill of the other physician. The trial court refused to give the instruction and the Supreme Court reversed the judgment on that account. In disposing of the case the court said: "The employment of Dr. Minor constituted an independent contract, and Dr. Keller is not responsible for his negligence or want of skill." The court cited in support of the opinion the case of *Myers v. Holborn*, 58 N. J. Law 193, 33 Atl. 389, where under somewhat similar circumstances the New Jersey court held that "a party employing a person who follows a distinct and independent occupation of his own is not responsible for the negligent or improper acts of the other."

This view of the law is based on the theory that the doctrine of respondeat superior applies only in case of the negligence of a servant who acts under the direction and control of the master, and does not apply to a physician or other professional man who, when employed, acts upon his own initiative and without direction from others. That idea was clearly expressed in the case of *Arkansas Midland R. Co. v. Pearson*, 98 Ark. 399, where it was said: "A physician cannot be regarded as an agent or servant in the usual sense of the term, since he is not, and necessarily cannot be, directed in the diagnosing of diseases and injuries and prescribing treatment therefor; his office being to exercise his best skill and judgment in such matters, without control from those by whom he is called or who pay his fees."

Applying this principle to the case in hand, it was held that as the defendant was not negligent in the performance of the operation, nor in the selection of a physician to continue the treatment after he left the city, he could not be held responsible for the negligence of the other physician who was left in charge merely because the other physician took charge on his suggestion and arrangement. For these reasons judgment for the plaintiff was reversed and the case remanded for a new trial.—*Norton v. Hefner*, Arkansas Supreme Court, 198 S. W. 97.

Doctor's Opinion as to Employee's Injuries Inducing Release.—The Iowa Supreme Court holds that the expression by an employee's doctor of an opinion concerning an employee's injuries was not a fraud invalidating a release thereby induced merely because other doctors did not share such opinion, especially where there was a difference of opinion between such other doctors.—*Seymour v. Chicago & N. W. R. Co.* (Iowa) 164 N. W. 352.

Military Medicine.

Italian Medical Activities in the War.—Dr. Victor G. Heiser, member of the American Red Cross Commission to Italy, read a paper at a meeting of the College of Physicians of Philadelphia, on January 2, 1918, supplementing the one presented before the American Association for the Advancement of Science (see page 69). It is generally understood, he said, that the Italian Army consists of at least 4,000,000 men and that the number of hospital beds is approximately 1,000,000. Just what it means in two years to expand a country's hospital service to these huge proportions can be better appreciated when it is recalled that in the entire United States, with a population almost three times as great as that of Italy, there are only 300,000 beds. In spite of this vast achievement the work accomplished by the Italian medical profession since the beginning of the war has attracted to itself but little attention in this country. While probably none of the Allies fighting in Europe have received less aid, other than financial, from outside their own borders, the medical men of Italy almost invariably were loath to speak of their achievements. The equipment for the care of the sick and wounded has been provided almost entirely in Italy. Mobile hospitals of 100 bed capacity, which can be taken down and transferred 75 miles and set up and put in service again within 24 hours, are in use; the entire equipment being transported on five camions (motor trucks) and three touring cars. New operations, particularly in dental and lung surgery, new instruments without number, have been developed. The Italian medical service is presided over by an official who has his office with the Minister for War at Rome. Under the chief medical officer there is stationed with each army a principal medical officer who has almost determining powers in directing the medical work of the army with which he is stationed. The care of the wounded is undertaken jointly by the Italian Red Cross and the Army Medical Service, medical aid being rendered through the following seven classes of agencies:

1. The *Posti di Medicazione*. These are the most advanced dressing stations for emergency service, and are located usually in dugouts in trenches very close to the front.

2. The *Sezioni di Sanità*. These are located one or two kilometers behind the front, are dispensaries and more fully equipped than the preceding.

3. *Ambulancia di Montagna*, located from two to five kilometers behind the front; the most advanced point reached by the Italian Red Cross.

4. The *Stazioni di Sanità* are somewhat larger and better equipped than the *Ambulancia di Montagna*.

5. The *Ospedali di Campo*, or Field Hospitals, are at accessible points somewhat farther back; of 500 bed capacity and are used also as distributing centers where cases are classified and sent to various special hospitals.

6. *Ospedali di Tappa* are base hospitals several hundred kilometers behind the lines with a bed capacity of from 20,000 to 40,000.

7. *Ospedali di Riserva* are institutions through-

out the cities of Italy which have been made available for soldiers.

For each army there are a number of large quarantine stations provided with steam disinfecting apparatus or sulphur-dioxide chambers. Every patient before admission to the general hospitals and all prisoners are passed through stations of this kind. Hospitals afforded by the Italian Red Cross consist largely of tourist hotels, schools, and other buildings adapted to the purpose; those provided by the medical service consist of existing army hospitals, military buildings, or entirely new structures. The latter are usually one-story pavilions about 14 feet high, 18 feet wide, of any desired length, constructed of angle iron placed on 6-foot centers, with the intervening space filled in with hollow tile resembling that used in fireproof construction in this country. The roofs are also of tile. They are cheaper than tentage, are cool in summer, and can be kept warm in winter. The decreased use of cavalry has made available large numbers of cavalry barracks. In one of these at Udine a single ward has 300 beds. Hospitals are being located increasingly nearer the front and in most unusual places. Thirty or 40 feet underground and directly under a point where a battle was raging, it was a novel experience to see the hospital routine in good operating rooms and wards supplied with artificial ventilation and modern hospital equipment. On the other extreme, at an elevation of 6,000 feet in the Dolomites, there was found a hospital of 30 bed capacity hewn out of the side of a cliff. The two sides and back wall were of stone, and the mountain range at this point was so narrow that through a hole bored in the back wall of the hospital it was possible to look into the Austrian trenches on the other side of the mountain. After receiving emergency treatment patients were sent to the rail-head on the marvelous teleferica, which often go from mountain-top to mountain-top over chasms thousands of feet deep.

Specialization has been carried to a high degree; at Udine the commission saw 1,500 fracture cases in a single hospital; at other hospitals there were only gunshot wounds of the chest. Speaking of the latter, Professor Morelli has invented an improved aspirator for draining fluid from the chest. Pressure within and without the lungs can be accurately read on a gauge and through the development of special technique, which among other things permits the lungs to remain collapsed during definite periods, he has been able to produce some startling results in lung surgery. In 100 recently completed cases there had been no mortality and Professor Morelli believes it entirely feasible to keep the mortality well under 5 per cent. in all gunshot wounds of the chest.

Practically every hospital throughout Italy has one or more *x-ray* machines, all manufactured in their own country. The smooth organization of the hospital train service was one of the most striking features which the commission saw in Italy. Often one would see a train back into a side track next to a hospital, take on board fully 350 wounded, and in less than thirty minutes proceed on its way. Everything worked with clock-

like precision. One is particularly impressed by the amount of new apparatus invented to meet the needs of war cripples and almost unbelievable progress has been made in appliances and methods for the reeducation of lost functions. Great stress is laid upon specialized forms of physical drill for rehabilitating nerve function and remarkable results were shown. Dr. Guali at the Villa Fiore has devised some remarkable improvements in artificial limbs, also a clever apparatus for registering the pressure of the artificial foot. At other institutions a trade suitable to the individual patient is taught. Italy has established huge stations for the return of her soldiers from Salonica and Albania. In view of 100,000 cases of malaria invalidated back, the importance of such quarantine stations is manifest. A comparatively small amount of tuberculosis has been encountered in the Italian army, but it is said that 30,000 tuberculous Italian prisoners had been returned from Austria. The x-ray diagnosis is a routine procedure in this disease. Among other activities with which the medical service is associated is an active reclamation department which provides for the collection and repair of articles found on the field after a battle. The very general employment of huge fireless cookers assures to the soldier absolutely hot meals in whatever position he is. Large shops for repairing these cookers form part of the system.

The prison camps at the front consist of barbed wire inclosures with good tents and excellent cooking arrangements. They are divided into three sections; the first being that in which the prisoners are bathed and their clothing disinfected; in the second, specimens of stools are taken for examination for cholera, dysentery, and typhoid. After three days those whose stools are negative are sent into the third section, where they stay until transferred to the interior. For the officers, houses of a semi-permanent character are provided. One is greatly impressed by the kindness and consideration shown prisoners of all classes. The food is the same as that given to the Italian officer or soldier of corresponding grade. No work is required of officers.

No official records of venereal diseases were available, but they are stated to have been reduced to almost negligible proportions. A complete medical school has been established near the front-line trenches. During the months when the army was comparatively inactive, all medical students in the service were ordered to San Giorgio di Nogaro, at which point professors from the various medical schools who are in the army also assembled, being assigned to look after the sick in the vicinity. This enabled them to use the clinical material for the benefit of the students. Finally it may be stated that the commission was much impressed by the excellent care given the wounded and the spirit of service manifested by the medical officers. They were on duty early and late and a wonderful fellowship and mutual helpfulness prevailed.

Roosevelt Base Hospital Quarantined.—A report from the American Army in France states that the entire Roosevelt base hospital was quarantined on January 9 because of a small outbreak of scarlet

fever, diphtheria, and mumps. Another militia contingent is also quarantined. The authorities emphasize that there is no epidemic and but few cases of contagious disease, but that isolation has been deemed advisable in order to take no chances of disease spreading.

Navy in Need of Binoculars, Spyglasses, and Telescopes.—The Navy Department makes an urgent appeal to patriotic citizens for loans of binoculars, spyglasses, telescopes, chronometers, and sextants. As the United States has hitherto relied upon foreign countries for its supply of articles of this kind it has no stock on hand to meet the present demand. Those having any of the above named articles which they can dispense with will be doing the Government a service by sending them to Franklin D. Roosevelt, Assistant Secretary of the Navy, Washington, D. C. Those that are accepted will be keyed, the name and address of the sender will be permanently recorded at the Navy Department, and every effort will be made to return them. As the Government cannot, under the law, accept service or materials without making payment therefor, one dollar will be paid for each article accepted.

Red Cross Expenditures.—A statement recently issued by Henry P. Davison, chairman of the Red Cross War Council, shows that since May 10, 1917, the membership of that body has increased from 486,394 to fully 22,000,000. The total amount collected by the national finance committee, through its 2,993 campaign committees, to December 28, 1917, was \$93,925,256. In addition there has been collected direct at the national headquarters \$3,319,352, making the total amount collected \$97,226,456. It is estimated conservatively that another six million dollars will be collected for this fund. The total amount of appropriations which the War Council has made and which have been approved by the executive committee to December 28, from the Red Cross war funds, aggregated \$75,329,764. The total amount appropriated for Red Cross work in France was \$37,445,613.

Dr. Irving David Steinhardt of New York City has been appointed by the Jewish Board for Welfare Work in the United States Army and Navy to deliver a course of lectures teaching sex hygiene to the camp workers of this organization at its headquarters in New York.

Innovations in War Surgery.—An announcement made by Surgeon General Bradley, who is with the American Army in France, to the Associated Press states that plans for the care of American soldiers involve a radical departure from former methods of caring for the wounded. Dr. J. M. T. Finney of Johns Hopkins University has devised a method that insures to each case continuous treatment from the dressing station on the fighting line through the various stations to the base hospital, and will do away with the frequent examinations of wound dressings under the methods hitherto employed. The American plan of using standardized splints, with the manual explaining it, has appealed to the medical men in the British Army as a great advance over the old way of allowing every surgeon to use splints of his own devising, and they have asked that the plan be adopted by the medical department of the British Army. The American expeditionary force has adopted the French ham-

mock litters, in which the wounded sit up, as the most efficient for removing the wounded from the trenches. Since the speedy treatment of wounds results in a greater saving of life, divisional ambulance sections have been mobilized to three-quarters of their strength. It is expected that this will result in almost a merging of the field and evacuation hospitals. Up to the present time only male nurses have been employed at advanced hospitals, but the new plans provide for female nurses there, since both the British and the French have found them valuable. It has become necessary to work out plans whereby men can be operated on more quickly than in former wars owing to the difference in the nature of the wounds. In previous wars most of the wounds were bullet wounds and it was not imperative to operate quickly, whereas in the present war most of the wounds are caused by shrapnel, which makes it advisable to operate as speedily as possible. This report from the American Army in France states that the sick chart follows very closely the weather record, going up when it is damp and stormy and falling when it is clear and cold. The sick rate of seasoned troops is slightly more than 2 per cent., while that of the newly landed is but slightly under 5 per cent. As the plans for caring for American wounded provide that when a man is found to be permanently unfit for service he is to be returned to the United States, ample hospital room is being obtained, and seventeen hospital trains have been ordered. Dr. George E. de Schweinitz of Philadelphia has charge of the care of the blind. Since it has been the experience of other armies that early treatment and instruction of the blind are most valuable, the plans for the care of American soldiers whose wounds result in blindness provide for instruction as soon after the wound is received as possible and will be continued by the army until these men reach the United States.

Offer to Care for Tuberculous Soldiers.—The National Jewish Hospital, which is situated in Denver, Col., has offered the institution to the Government for the care of tuberculous soldiers. The hospital now has accommodations for 150 patients. In order to avoid turning out civil patients in need of treatment Mr. Grabfelder, the head of the institution, has offered to finance the building of a tent colony on the grounds of the hospital. The institution now maintains schools and employment offices on its grounds and has a rule providing that no patient who has been cured shall leave the hospital until he is assured of being able to earn a livelihood. It is pointed out that this would mean a great deal in the readjustment of soldiers to civil life.

Value of Psychological Tests Demonstrated.—An incident that occurred recently at Camp Dix serves to show that the psychological tests as to mental fitness for military service are of practical value. When the chief examiner of the psychological department needed a staff of clerks and assistants he asked the division headquarters to assign the necessary men from the depot brigade. The authorities told him he might have the whole brigade from which to choose. As a result 600 men were subjected to the psychological tests and the 80 highest were chosen for department service without knowing their occupations or military rank. It was

found that by the test the examiners had practically stripped the organization of the men who saw that the orders from the officers were carried out by the men in the ranks, and that it was necessary to make some other adjustment. Such a finding as this is regarded as highly satisfactory from two standpoints. It has given great satisfaction to the men interested in the psychological tests as a proof of the accuracy of these tests and it is also a compliment to the system that enables line officers to pick for important positions men whose mental scores were later shown to be of high average. However, the psychologists claim that their method has the advantage on its side since it enables them to make a successful choice in fifty minutes, whereas it takes the officers a number of weeks to make a suitable selection.

Health of Camp Dix Good.—Major-General Scott has issued an official denial of the reports to the effect that health conditions at Camp Dix are bad. He states that the health conditions of the camp are better than those of civil life, and better than those of most army posts in times of peace. He states that there are not more than 100 cases of illness in the whole camp that physicians in civil life would consider sufficiently serious to confine a man to his home. There have been only 18 deaths in the camp since it started, and of these 11 were due to various general diseases. Nevertheless a quarantine of the camp became effective on January 13 owing to the prevalence of measles. On January 12 there were 56 cases in the camp. While many of the camps have a much larger number of cases of measles, this institution of quarantine has been deemed advisable as a precautionary measure designed to limit the spread of the disease.

Major Grayson M. P. Murphy of New York has resigned as head of the American Red Cross Commission to Europe. It is reported that he will return to service in the American Army. Major James W. Perkins of New York, who has been serving with the American Red Cross Commission in Europe since last June, will immediately take up the direction of the commission's work.

Drafted Men Must Submit to Operation.—The manual of the army medical department, issued in 1916, provides for the discharge of men where the surgeon is in doubt whether the proposed operation involves an appreciable risk to the life of the soldier. It seems that many drafted men have been taking advantage of this provision to evade military service, so that Surgeon General Gorgas has found it necessary to issue a new order. Under this order any soldier whose physical condition makes him unfit to discharge his military duties must submit to an operation if such operation is indicated, or face court martial if a board of medical officers so rules. The new order directs, "in cases in which a soldier refuses to submit to operations or medical treatment that a board of medical officers be convened to pass upon the case and if the board is of the opinion that the operation or treatment is necessary to enable the soldier to properly discharge his military duties, and he persists in his refusal after being notified of the opinion of the board, he may be tried under court martial under the 96th article of war."

SERUM THERAPY OF PARTIAL TETANUS.

CASES of partial tetanus are usually instances of attenuated tetanus as is made evident by the long duration of incubation, the limited localization of the symptoms, and the relative benignity of the process. It, therefore, is manifest that for an affection usually much less serious than generalized tetanus, our means of treatment will be much more efficacious. In partial tetanus, which often tends toward a spontaneous recovery, the slightest aid given to the *natura medicatrix* will make the scales tip in favor of a cure. Given the almost absolute uselessness of curative serotherapy in acute tetanus, as demonstrated in the present war, this method of treatment has been practically given up by the French surgeons, but it should be added that antitetanic serum is believed to possess an absolute preventive action.

This latter proposition, however, does not seem to be true, as is pointed out by Fricker in his very excellent thesis (Lyons, March, 1916) on the serotherapeutic treatment of partial tetanus, and he shows by numerous case reports that tardy partial tetanus "can perfectly well develop in spite of a former prophylactic injection of serum. Although in the majority of these cases the tetanus is attenuated by the prophylactic injection, it is, nevertheless, true that the first part of the above proposition is not exact." Fricker is also of the opinion that belief in the non-curative action of serum is not in conformity to facts. Considering the numerous failures in acute generalized tetanus, surgeons have concluded that curative serotherapy is useless and have substituted a certain number of medications in its place. Large doses of chloral, Baccelli's treatment with subcutaneous carbolic acid injections, and intraspinal injections of magnesium sulphate have each been essayed without any appreciable success. It is above all in types with a rapid evolution, where the tetanic toxin is already fixed in the nervous centers and can no longer be neutralized, that antitetanic serum fails. But on the contrary, in partial tetanus, which represents the chronic form of the process, the action of antitetanic serum is always certain, because the conditions of its action are quite different from those in

the acute generalized form of the disease. From personal experience the author is of the opinion that antitetanic serum has a very effective action in the chronic forms of tetanus, certainly far more so than other methods of treatment.

The very important question of anaphylactic accidents remains to be considered. To pass in review all the expedients that have been essayed for avoiding anaphylactic shock would make a volume, but it seems to us that from this viewpoint the question of the selection of the channel employed for the introduction of the injection is by no means a matter of indifference. Of late intravenous and intraspinal injections have been particularly proved as being more active. Now, the intravenous route would seem to be more capable of giving rise to anaphylactic shock, and this certainly is the means resorted to in animal experimentation for its production. In these circumstances, and knowing that the intravenous route does not appear to offer a therapeutic action superior to other channels of injection, this procedure should, according to Fricker, be rejected as dangerous. As to the intraspinal route, he is also of the opinion that it is not to be recommended, because it very readily gives rise to anaphylactic shock, as has frequently been observed during the serum treatment of cerebrospinal meningitis, or even to accidents of cardiac collapse of a very serious nature. But, although in cerebrospinal meningitis this route is the only efficacious one, the same cannot be said of tetanus in which the superiority of intraspinal injections has been by no means demonstrated. There remains the subcutaneous route, which Fricker says is the one of choice. Its action is quite as certain as that of the other procedures, and it exposes the patient much less to anaphylactic accidents. To still further diminish their chance of occurrence, it would seem that small doses of 5 c.c. given daily for some time produce the best results. The author finds that the treatment of late partial tetanus by serotherapy in no way prevents the use of other therapeutic measures. Chloral and morphine in particular should always be exhibited and will aid greatly in recovery, but what he regards as essential to remember is that in the cases in question antitetanic serum possesses a sure curative action.

TREATMENT OF MALARIA BY QUININE-ADRENALIN HYPODERMOCLYSIS.

THE difficulty in curing a nominally curable affection is well illustrated in the history of the therapeutics of malaria, and especially during the present war when the disease has shown itself peculiarly rebellious to treatment. This quinine-resistant type of disease is not to be confounded with the malignant and lethal types encountered in certain tropical countries. It is rather a continually relapsing malaria which, if not relieved, will become inveterate. This change of type appears to be due wholly to external conditions which result from the state of

war, and no one doubts that under peace conditions the ordinary prophylactic dose of quinine *per os* would suppress the disease manifestations.

Professor Pende of Palermo, now in charge of a Military Hospital at Padua, advocates in *Il Policlinico* for November 4 the early routine use of quinine-adrenalin hypodermoclysis for malaria-stricken soldiers. He would have the latter isolated in special hospitals in malaria-free regions, and then submitted to this intensive and sterilizing form of treatment which should enable them to return to the front for active service without any prolonged interval of convalescence.

Quinine by the mouth has proved very disappointing in this respect and this experience is by no means confined to Italy, for the French medical men on the Macedonian front, conceiving that the negative results were due to low dosage, gave quinine in heroic quantities to no purpose. The hypodermic and intramuscular injection of quinine involves an enormous consumption of the drug with a relatively small showing in positive results. The same thing may be said of the intravenous use, for in order to cure an obstinate case from 12 to 20 daily injections have been necessary; and while the dose is not such a factor here, such extensive use of a minor surgical resource is not adapted to camp practice.

The author has, therefore, introduced a *sterilisatio magna* in which 250 c.c. of physiological saline solution is infused beneath the skin of the flank every 5 or 6 days, the total number of infusions being 4 or 5. To this infusion are added 2 gm. of quinine bichloride (equal to 1.64 gm. of alkaloid) and 0.5 c.c. of commercial solution of adrenalin 1 to 1,000. He has had a very extensive experience with this resource and finds that it is extremely well tolerated. The remedy is rapidly absorbed as shown by urinary tests. The improvement is so pronounced with the continuation of the infusions that it is safe after the stated number has been given to administer the drug by the mouth. Thus far the remedy has not been tested in chronic malaria. The author has used blood tests throughout as a criterion of cure.

NEOPLASTIC FEVER.

THAT fever and even hyperthermia may sometimes accompany the evolution of malignant tumors is well known, but in such cases it is by no means easy to convince oneself that this phenomenon is due directly to the tumor, *i.e.* to substances produced by the latter which can act on the heat center. If this was true fever would be the rule and not exceptional. Hence febrile cases of neoplasm should be studied individually with great care.

In *La Riforma Medica* for December 8, Pedrini reports four cases. The first was in a laborer of 53 who presented severe constitutional symptoms—emaciation, asthenia, a yellowish tint of the skin, etc., of four months' standing. Physical examination revealed a slight enlargement of the liver with ascites, which was tapped, giving exit to 10 liters

of serosanguineous fluid. The patient ran a temperature of 99° to 100.5° throughout the observation period and up to his death. Autopsy revealed an isolated cancer of the liver. The significance of this case was not great for fever has often been noted in sclerotic processes in the liver, malaria sometimes being simulated. Neither in these cases nor in the pseudomalarial fever, which sometimes accompanies pyloric cancer with retention, can the fever be regarded as of essentially neoplastic origin.

In Pedrini's second case, pleuropulmonary cancer in a young man, with incidental hydrothorax, was associated throughout with fever of 99.5° to 101.3°. As long as the pleuritis was regarded as inflammatory in type the rise of temperature was accounted for. The third neoplastic fever patient had a primary prepyloric cancer with extensive metastases to the liver, while in a fourth the seat of the neoplasm was the cervix uteri. The author concludes that there is no typical neoplastic fever. Of a primary fever due to the evolution of the tumor we have little direct evidence. Secondary fever is doubtless due to some secondary infectious or toxic process dependent upon the presence of the cancer, for the latter can of course readily interfere with drainage.

In regard to a primary process, one may ask to what extent fever is suggestive of the presence of latent or obscure cancer. In a subject of cancer age an apparently unmotivated fever might suggest that the presence of a neoplasm had activated an old focus of infection or by interfering with drainage had caused a local stasis and absorption of thermogenic material. In material like the author's other evidences of severe disease were so pronounced that the mere presence of fever of low or medium grade was in nowise of major significance.

IODINE IN THE TREATMENT OF PHTHISIS.

JOBLINS and Petersen, when making investigations at the Rockefeller Institute, found that soaps of the unsaturated fatty acids were capable of inhibiting the action of trypsin and other ferments, and furthermore they discovered in tubercle bacilli a ferment-inhibiting substance of the nature of a lipid, to which they attribute the lack of autolysis and consequent caseation in tuberculosis. In addition, they found the higher the iodine value of a soap the less was its activity as an inhibiting agent, while saturation with iodine would destroy entirely its inhibiting powers. Moreover, in a further study these same investigators demonstrated that ether-soluble substances of the bacilli, which constitute from 25 to 35 per cent. of their work, and which are largely composed of fatty acids, have a marked restraining action on trypsin.

Dr. E. Curtin, writing in the *Medical Press*, Nov. 14, 1917, draws attention to the above investigations and points out their significance. Iodine counteracts and inhibits the lipid element, which acts as an antiferment. The effect of iodine is supposed

to be due to a saturation of the unsaturated bonds of the fatty acids of the lipoids, rendering the substituted product less active as an antipyretic agent. It also reduces the surface tension of the phagocyte and increases phagocytosis. According to Curtin, Dr. Crofton of Dublin has shown that iodine attacks the toxin of the microbe, turning it into a toxoid, and this facilitates the digestion of the microbe.

The conclusions drawn by the author are as follows: (1) The ferment-inhibiting action of the tubercle bacillus is due to the presence of unsaturated fatty acids. (2) These fatty acid compounds can be removed by means of ether. (3) Iodine and iodide of potassium remove or modify the inhibiting action of tubercle bacilli. Curtin points out the above observations confirm and justify the treatment of phthisis by the intravenous injection of iodoform dissolved in ether, a treatment employed by him with, he claims, unvarying success during a period of nearly six years.

CLEMENCEAU'S INAUGURAL THESIS.

FEW people in this country know that Georges Clemenceau, the present French premier, and perhaps the strongest figure among the French people, is a graduate physician. This fact is duly honored in the bulletin of *Le Progrès Médical* for December 1. Clemenceau was a pupil of Charles Robin, one of the most versatile physicians and prolific writers of his day, whose fame rests chiefly on his anatomical works. On May 13, 1865, Georges Benjamin Clemenceau, who had served as interne in the hospitals of Paris and Nantes, sustained his Paris thesis, which was entitled *de la génération des éléments anatomiques*, before a jury composed of Charles Robin, Pajot, Sée, and Parrot, all unusually distinguished men. Not much is known of his defense or of the rank of the thesis, but it was a work of 224 pages, which even to-day conveys a very favorable impression. Merklen wrote a review of it in 1914 and some of his comments are reproduced in the article above mentioned. Both normal and morbid anatomy are considered, and the view is upheld that disease is not an entity, separate from the body, but only an alteration of physiological processes.

Merklen sums up the work as made up of embryogeny and medical philosophy. Of the four chapters three deal with the ovum and embryo. The accumulation of facts involved much labor and the volume paved the way for the author's later works, such as "La Mêlée sociale." In his thesis he defined man as a "federation of anatomical elements," and this view is upheld in his subsequent philosophy. Grappe, Clemenceau's biographer, styles him a physician in literature, whose scientific training made him exact, and he lays a great deal of stress on the thesis above mentioned as a revealer of the author's temperament which was to be revealed anew thirty years later in his philosophical writings.

COMMON COLDS AND PNEUMONIA.

APPREHENSION lest an ordinary cold in the head may develop into pneumonia is a fear shared not only by the laity, but by many physicians as well. That this fear is not without some justification is evidenced by the fact that an appreciable number of cases of infection of the upper respiratory tract are followed sooner or later by typical lobar pneumonia. Whether this sequence is to be explained on the *post hoc ergo propter hoc* argument or is merely one of coincidence remains to be elucidated by scientific study. As a contribution in this direction Eugenia Valentine, working in the Bureau of Laboratories of the Department of Health of this city, gives the result of an investigation to ascertain the type of pneumococcus present in persons suffering from so-called common colds (*Journal of Experimental Medicine*, January, 1918). The method of procedure was to inject some of the nasal secretion or sputum into mice. A total of 65 patients afflicted with colds were examined. Pneumococci were found in 37 out of the 65 cases by animal inoculation. By direct plating of the secretions on blood agar, 6 more cases were found to contain this organism. Of these 43 positive cases, 2 contained pneumococci belonging to Group I; 2 to Group II; 4 to Group III, and 35 to Group IV. The two patients harboring Group II pneumococci and one with the *Pneumococcus mucosus* of Group III had been in contact with cases of pneumonia. The two cases belonging to Group I exhibited evidence of prostration and had a temperature of 102°. Direct plating of the secretions obtained from these patients demonstrated that Group I pneumococcus constituted at least 75 per cent. of the organisms present. As a result of these observations the author concludes that common colds due to Groups I and III pneumococci must be looked upon as a possible source of contagion for others, or as sources of possible autogenic cases of pneumonia. All of which is a further plea in favor of treating a cold not only as a menace to the possessor, but also, and what is most important to the community at large, as a potential source of danger to others.

IS THE PRACTITIONER RESPONSIBLE FOR ARTICLES LEFT IN HIS WAITING ROOM?

THE medical profession in France has been shocked by the decision of an Italian appellate court of justice to the effect that a practitioner is responsible for the safety of the wraps, etc., left in the waiting room by his clients, provided that he has failed to use ordinary precautions for their safe keeping. The editor of *La Presse Médicale* for November 19 in noting this decision states that it would work havoc if enforced in France. For self-protection it would be necessary to install during consultation hours a cloakroom with a presiding functionary and checks. The obligation would little by little be transferred to lawyers, architects, and other professional men who might be called upon to check the overcoats and canes of clients. Is there an implied contract that the medical practitioner is responsible for articles left in his vestibule by patients who enter the consultation room? If so, how much vigilance is he supposed to exert? Is the responsibility to equal that imposed on the innkeep-

ers? This question has already been answered in the negative by the French courts. Even restaurant keepers in France are not legally responsible for coats, hats, bicycles, etc. Special services of deposit of personal belongings exist in theaters and museums, and therefore there is an implied contract of responsibility, but no such conditions are to be found in department stores, factories, sleeping cars, etc., which protect packages, hand baggage, and workmen's tools. The physician cannot renounce all responsibility, and in cities he usually has a waiting room attendant who acts as custodian of clients' belongings. In the small town and rural districts such precautions are hardly required.

News of the Week.

Columbia University Plans Pay Diagnostic Clinic.—The trustees of Columbia University announce that plans are under consideration for the establishment of a large diagnostic clinic which will meet the needs of the middle classes who do not wish to be the recipients of charity and yet cannot afford to pay the fees of a number of specialists whose services may be necessary in order to reach a diagnosis. It is hoped that the clinic may be able to act as a distributing station for a number of hospitals. Dean Samuel W. Lambert, in presenting this proposal, states that he anticipates that there will be considerable opposition to it from the rank and file of the profession, but explains that the plan does not propose to eliminate the family physician. The clinic proposes merely to make the diagnosis and then refer the patient to his family physician for treatment, supplying special advice or suggestions if they are needed. The financial arrangements provide that every clinical worker shall be paid and that the fees charged patient shall be commensurate with their incomes. At the same time that these plans were made public it was announced that the trustees contemplated adding a fifth year to the medical course. During this additional year the candidate for licensure will work in a hospital under college discipline. Plans are also under way providing for additional graduate instruction and research work.

Diet Squad Tries Out School Lunches.—An experiment is being conducted under the cooperative management of the Post Graduate Hospital, the People's Institute, and the New York School Lunch Committee, the object of which is to demonstrate what constitutes a proper school lunch and to show the advantage of such a lunch to school children. The present investigations, which have shown an alarming amount of undernutrition among school children, have also indicated that this condition of affairs is not due so much to poverty as to a lack of knowledge of food values and of what constitutes proper food for growing children. The subjects of the present experiments are 27 boys, belonging to Public School No. 40., who are of various nationalities and range in age from nine to twelve years. The lunches consist in a well-balanced ration of 900 calories. It is hoped that the results of this experiment will serve as a basis for a national campaign to make an adequate school lunch a civic necessity.

State Federation of Labor Urges Health Insur-

ance.—At a conference of representatives of the State Federation of Labor held in Albany, on January 8, a legislative program was adopted whereby this organization will endeavor to promote legislation for the establishment of a State administered health insurance for wage earners. The federation favors the creation of a bureau of sickness prevention and health promotion within the State Industrial Commission.

Court Upholds Law Against Birth Control Propaganda.—The Court of Appeals to which Mrs. Margaret Sangster, who was convicted in the lower courts of violating the section of the penal law prohibiting the dissemination of birth control information or paraphernalia, carried her case has handed down a decision declaring the law constitutional and that it must, therefore, be upheld by the courts.

New Health Commissioner for New York City.—Mayor Hylan has appointed Dr. J. Lewis Amster of the Bronx health commissioner of the city to succeed Dr. Haven Emerson. Dr. Amster is a graduate of Cornell University Medical School in 1902.

Physicians Get City Appointments.—Mayor Hylan has appointed the following physicians, who were formerly on the coroners' staffs, assistant medical examiners at salaries of \$3,000, except in the Borough of Richmond, where the salaries are only a little over half that amount: Drs. George W. Tong, Albert T. Weston, George Wuest, Timothy D. Lehane, Benjamin Schwartz, William H. Nammack, John Riegelman, Thomas Curtain, George Hart and George Mord.

Course of Instruction in Contagious Diseases.—The Health Department of New York City announces that the course of instruction in contagious diseases which it has given at the Willard Parker Hospital have been so well attended that it has arranged to give a similar course at the Kingston Avenue Hospital, Brooklyn. Each course will consist of eight lessons, of which six will be devoted to clinical or bedside instruction, one to a demonstration of intubation, and one to practical laboratory work. The sections will be strictly limited to ten members each. No fees are charged, but physicians entering the courses are expected to attend regularly. The course will be given Tuesdays, Wednesdays, Thursdays, and Fridays, at 3 o'clock. The first course will be given on Tuesday, February 5. Physicians may register for the course with the Bureau of Public Health Education, Department of Health, 139 Center Street, New York. A series of courses similar to those given in previous years will be given at the Willard Parker Hospital. The schedule for these lectures has not yet been definitely arranged.

New York City's Death Rate.—In a report recently submitted to ex-Mayor Mitchel covering the work of the Health Department for four years Health Commissioner Emerson calls attention to the fact that since 1910 the death rate of the city has dropped from 16 per thousand population to 13.78 per thousand. Under the Fusion administration, that is during the past four years, the rate has dropped from 14.03 to 13.78. This report shows that the decrease in the death rate is chiefly in the matter of the infant mortality. In 1910 slightly

more than 125 infants under one year of age out of every 1,000 births died, while during the past year less than 90 children per 1,000 births died.

Associated Out-Patient Clinics of the City of New York.—The annual meeting of this organization will be held on Friday, January 25, at 8.15 P. M. in the lecture room of the Presbyterian Hospital, 41 East Seventieth Street. A paper on "Voluntary Workers in Dispensaries" will be read by Dr. Charles Hendee Smith; one on the "Malnutrition Clinics and the Work of the Poliomyelitis Clinics" will be read by Dr. E. H. Lewinski-Corwin, executive secretary. "Dispensary problems Growing Out of the War" will be another topic for discussion, but the speaker for this subject has not as yet been announced.

The Ophthalmological Society of the United Kingdom will hold its next Annual Congress at the Royal Society of Medicine, London, England, on May 2, 3, and 4, 1918. E. Treacher Collins, F.R.C.S., is president of the society and M. S. Mayou, 30 Cavendish Square, London, W., is secretary.

The Clinical Society of the Dispensary and Hospital for Deformities and Joint Diseases, New York, will hold its next meeting at the dispensary building, 43 East 123rd Street, at 8.30 o'clock, on January 22. The meetings of this society are held every second and fourth Tuesday of each month.

The Volusia County Medical Society, which met recently at Hawk's Point, Fla., elected the following officers: *President*, Dr. F. J. Walter of DeLand; *Vice-Presidents*, Dr. W. C. Chewing and Dr. R. R. Niblack of New Smyrna; *Secretary-Treasurer*, Dr. L. C. Ingram of DeLand.

The Dallas County Medical Society, which met at Dallas, on December 27, elected the following officers: *President*, Dr. J. T. Watson; *Vice-President*, Dr. Minnie Massett; *Secretary-Treasurer*, Dr. R. S. Loving.

Obituary Notes.—Dr. EDWARD HOMER MARTIN of Middlebury, Vt., died in the Mary Fletcher Hospital in Burlington, on December 29, aged 56 years. He was graduated from the University of Vermont Medical School, in 1884. He was surgeon to the Mary Fletcher Hospital and to the Fanny Allen Hospital at Winooski. Dr. Martin was treasurer of the Vermont State Medical Association and secretary and treasurer of the Addison County Medical Society.

Dr. FREDERIC POWERS of Westport, Conn., died on January 12, of cerebral hemorrhage. He was born at Amenia, Dutchess Co., N. Y., May 15, 1842, and was a graduate of the College of Physicians and Surgeons, New York, in 1870. He was a member of the Fairfield County and Connecticut State Medical Societies, of the American Medical Association, and of the Alumni Association of the College of Physicians and Surgeons. He practised medicine for over 40 years in Westport, Conn., where for many years he was health officer and medical examiner.

Dr. FRANK E. BURDICK of Providence, R. I., died suddenly of heart disease at his home, on December 26, aged 46 years. He was graduated from the Syracuse College of Medicine, New York, in 1895. He was a member of the staff of the Rhode Island Hospital and visiting physician at St. Elizabeth's Home.

Dr. OMER LARUE, a graduate of the Victoria University Medical Department, Quebec, in 1872, died at his home in Putnam, Conn., on December 28, aged 68 years. He was a charter member and former treasurer of the Franco-American Historical Society of the United States and a former president of the Winham County Medical Association.

Dr. JOSEPH H. HORNER of Concordville, Pa., a graduate of Jefferson Medical College, in 1886, died at Columbus, Ohio, on December 27, aged 73 years.

Dr. CHARLES W. HOYT died, after a long illness, at his home in Sharon, Pa., on December 15, at the age of 78 years. He was a graduate of the Cleveland Homeopathic College in 1870, and a Civil War Veteran.

Obituary.

THOMAS DAVISON CROTHERS, M.D.

HARTFORD, CONN.

DR. THOMAS D. CROTHERS died at Walnut Lodge Hospital, Hartford, on January 13, of pneumonia. He was born at West Charlton, N. Y., September 21, 1842, and was graduated from the Albany Medical College in 1865. He began practice in West Galway, but removed to Albany in 1870, where he was appointed assistant professor of the practice of medicine in the Albany Medical College. In 1875 he was appointed assistant physician to the New York Inebriate Asylum at Binghamton. In 1878 he was made superintendent of the Walnut Hill Asylum in Hartford, and when it became the Walnut Lodge Hospital in 1880 he was chosen president and superintendent, and remained there until his death. He was editor of the *Journal of Inebriety* from 1876. For some time he was dean and professor of nervous and mental diseases at the College of Physicians and Surgeons, Boston. Dr. Crothers' specialty was the study and treatment of inebriety and drug addiction, and to this he had devoted his entire professional life. His published works were: "The Disease of Inebriety," 1893; "Drug Habits and Their Treatment," 1901; "Morphinism and Other Drug Diseases," 1902; "Clinical Study of Inebriety," 1911; he was also a frequent contributor on topics related to his specialty to various medical journals. He was secretary of the Association for the Study and Care of Inebriates, and was a member of a number of medical societies, including the American Medical Association.

Correspondence.

ONLY GRADUATE NURSES ELIGIBLE FOR ARMY SERVICE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the recent publicity announcement sent you, relative to the need of army nurses, it was stated that the call to duty was made to all graduate and practical nurses in the United States. The Surgeon General directs me to inform you that the statement relative to practical nurses was erroneous, as I am informed by the superintendent of the Army Nurse Corps that only graduate nurses would be accepted for service. Will you kindly make this correction?

C. D. CRUDGINTON,

1st Lieut. Sanitary Corps, U. S. N. A.

CHRISTIAN SCIENTISTS ARE NOT ANTAGONISTIC TO THE RED CROSS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In relation to the item in your January 5 issue, taken from the *New York Times*, to the effect that a Red Cross booth was torn down by Christian Scientists at their Wednesday evening meeting in Aeolian Hall, please permit me to say the statement is unqualifiedly false. The booth placed in the lobby before the meeting remained there throughout the meeting, and the woman in charge solicited and received members to the Red Cross among those in attendance without molestation, before and after. I have this upon the written statement of the first reader, the chief usher, the assistant usher in charge of the hall, and an attendant at the meeting. On December 22 the *Times* published a refutation of the story by Mr. Frank Presbrey, the leader of the Red Cross drive, who gave out the original story.

Equally false is any intimation that the Christian Science organization is opposed to the work of the Red Cross. A complete answer to this charge is found in the fact that the Red Cross helpers were invited to join the relief train sent by the Christian Science Board of Directors of the Mother Church in Boston to the Halifax sufferers, and accepted the invitation. Among Christian Scientists membership in the Red Cross is wholly a matter of individual option. May I say for myself that I have been a member nearly three years.

ALBERT GILMORE.

LETTER FROM CANADA.

(From an Occasional Correspondent.)

CARE OF INVALID SOLDIERS—WORK OF THE MILITARY HOSPITALS COMMISSION—THE HALIFAX DISASTER—LIABILITY OF MEDICAL STUDENTS FOR COMBATANT SERVICE.

TORONTO, January 2, 1918.

OFFICIAL announcement was recently made of the appointment of Lieut.-Col. Alfred Thompson, M.D., medical superintendent of the Military Hospitals Commission and M. P. for the Yukon, as assistant director of Medical Services, Invalids. Lieutenant-Colonel Thompson will thus have charge of the medical service of the hospitals and convalescent homes established by the Military Hospitals Commission, and will carry on his duties under the direction of General Fotheringham, C. M. G., the director general of Medical Services.

Within a few months of Canada's entry into the war the majority of the members of the Army Medical Corps had gone overseas, and the acting director of Medical Services, Colonel Potter, was left with a staff greatly depleted and a superabundance of work. In addition to the great mass of clerical work and the medical administration of the different military districts throughout the Dominion, provision had to be made for the medical care of members of the Expeditionary Force, and particularly for the care and treatment of wounded and invalided soldiers upon their return to Canada. In the summer of 1915, therefore, the Military Hospitals Commission was established, under the chairmanship of Sir James Lougheed. The commission was composed of representative men from the vari-

ous provinces who were in a position to influence the municipal and provincial bodies to cooperate with the federal government, and who understood the facilities offered by each district and province. Thus the work of providing facilities for the care, treatment and reeducation of invalid soldiers was coordinated. The establishment of hospitals and convalescent homes was placed in the hands of the commission, and there was a general understanding that whereas the Army Medical Corps would provide medical care and treatment for members of the Canadian Expeditionary Force who had not yet left Canada, the commission was to assume responsibility for the care and treatment of returned invalid soldiers. This arrangement led to a good deal of duplication, particularly in view of the fact that the treatment of men was commenced overseas under the direction of the Army Medical Service, and upon their return to Canada taken over by the commission, which entailed the establishment of a double service in each district, an arrangement all the more to be deplored when the services of medical men were so much in demand. It was felt, therefore, that it would be better were an arrangement made whereby the purely medical part of the vast amount of work to be done could be placed in the hands of the army medical authorities, and the efforts of the commission, which had already done such valuable work, directed toward the establishment of convalescent homes, the provision of vocational training, etc. The matter has been under consideration for some months, and official announcement has now been made as follows:

The Military Hospitals Commission which has been charged with very full powers in connection with returned soldiers, has found itself confronted with many serious problems. The number of men in its institutions has about quadrupled within the year, being at present about 11,000, with a probable increase before the new year to 15,000. The heavy fighting which has recently taken place will unfortunately greatly increase this number. The Commission has been able fairly to keep abreast and somewhat in advance of the requirements of the invalids, in providing accommodation and equipment. Its greatest problem has been to arrange adequate medical and surgical treatment for these invalids. This has arisen from the following causes: The fact that so large a proportion of the medical men of the country have placed their services freely at the disposal of the military authorities; again the urgent demand for medical men at and near the front; again the fact that treatment of those wounded or invalided in warfare has made enormous strides through experience gained since the beginning of this war. Consequently, the best treatment of the invalids who return to Canada, requires that the treatment should, at least in part, be given by men who have had overseas experience. To meet the situation it has been arranged between the Department of Militia and Defence and the Military Hospitals Commission as follows: That the medical services in the institutions of the Commission shall be performed by the Army Medical Corps of the Department of Militia and Defence. Lieutenant-Colonel Alfred Thompson, medical superintendent of the Commission, will receive a staff appointment as Assistant-Director of Medical Services, Invalids. He will, under the Director-General of Medical Services, carry on this work with a staff selected from the Army Medical Corps. The Militia Department will make arrangements by which the present medical staff can be retained. The office of Lieutenant-Colonel Thompson, A.D.M.S. Invalids, will continue to be at the headquarters of the Military Hospitals Commission. There will thus be linked together, in caring for those invalids, the Military Hospitals Commission and the Army Medical Service Corps.

Since its establishment the Military Hospitals Commission has accomplished a most important and extensive work. It has established throughout the Dominion a series of convalescent hospitals equipped with every facility for the treatment and reeducation, both functional and vocational, of invalid soldiers. It has also established the Orthopedic Hospital in Toronto, and has taken over Hart House, where research work in this connection is being done, and training is given in massage and the use of various appliances employed in functional reeducation. Some account of this work was given in my previous letter.

Although it is not possible yet to state with any degree of certainty the number of lives that were lost in the disaster which overwhelmed the city of Halifax on the morning of December 6 last, it may be said that the loss of property is approximately \$20,000,000, two square miles of buildings having been completely wrecked. The number of those injured is estimated at about 3,000; those killed at about 1,250; and those partially or totally blinded at about 350. The large number of eye injuries was due to the fact that practically every pane of glass in the city was smashed by the force of the explosion and bits of glass were sent flying in all directions.

In the confusion which followed immediately upon the explosion it was natural that every one should run for help to the medical men in the city, whose offices were crowded with people, injured and non-injured, those who had escaped trying to assist those who were hurt or to find missing ones. Under such conditions it was extremely difficult for doctors to attend to the wounded, and many of them worked continuously for thirty-six hours or more.

The hospitals also were filled with wounded, who were brought in by hundreds every hour, some of them with eighteen or twenty distinct wounds, in many cases of the scalp and eyes, caused by falling wreckage or bits of flying glass. One of the most painful aspects of the catastrophe was the fact that many were buried under fallen buildings and could not be rescued on account of the fires which followed close upon the explosion and the subsequent blizzard and heavy snowfall.

Col. McKelvey Bell, A. D. M. S., of the Sixth Military District, in which Halifax lies, at once took command of the situation and directed the work of rescue. The promptness and efficiency with which he acted prevented worse developments in a situation that was already almost beyond description, and within a few days of the disaster Colonel Bell had appointed a committee of administration, instituted daily reports from the various hospitals and daily inspection of all hospitals and dressing stations, and had appointed an officer to take charge of all available statistics, and another to direct transportation.

At the University of Dalhousie the students had just assembled for the classes, which commenced at nine o'clock, when suddenly, with a tremendous roar, every window in the medical building was blown in. The laboratories fared even worse, particularly those of physiological chemistry, histology, and biology, since not only were the windows blown in but the ceilings also fell.

Prof. Fraser Harris of the Chair of Physiology in Dalhousie University, has been appointed historian of the medical side of the disaster, and is

preparing a complete report from this point of view.

Prompt assistance was sent to the stricken city from near-by towns and from Montreal, Toronto, and other places, and the following units were sent from the United States with as much dispatch as possible: (1) The Massachusetts State Guard from Boston, with a personnel of thirty-two, commanded by Maj. Harold J. Gidding. This was assigned to the building known as Bellevue, once the residence of the general commanding the Halifax garrison. (2) Dr. E. A. Codman's private hospital staff from Boston. This comprised fourteen persons, and was sent to the Y. M. C. A. Building, which had been rapidly transformed into an hospital. (3) The American Red Cross Unit from Providence, R. I., made up of one hundred and seven persons, commanded by Maj. G. de N. Hough. This unit worked at first in the Halifax Infirmary and later at Bellevue. (4) The American Red Cross Unit (Boston) No. 5, consisting of one hundred and five persons, in charge of Dr. W. E. Ladd and Mr. Samuel L. N. Wolcott (A. R. C.). They went to St. Mary's College, a Roman Catholic institution, hurriedly transformed into an emergency hospital. (5) The State of Maine medical unit, consisting of twenty-four persons, commanded by Maj. Gilbert M. Elliott. They went to the Halifax Ladies' College, which had also been given over as a hospital. (6) The Calais Chapter of the A. R. C. from Calais, with a personnel of twelve, under command of Dr. William Miner and the Rev. R. A. Macdonald. This unit worked chiefly at relief dressing stations No. 1 and No. 2. Quantities of food, clothing, and medical supplies were sent to Halifax from different places in Canada and the United States, and on the afternoon of the day of the explosion Captain Goodman left New York on a special train to coordinate the work of the American and Canadian Red Cross, taking with him four baggage cars of supplies.

Fortunately, many eye injuries, though severe, have cleared up under treatment, but, as already stated, the number of those who have lost their sight is very great. Three cases of gas gangrene were met with, and one case of incipient tetanus, which, however, was arrested by the free injection of anti-tetanic serum.

Since the entry of Canada into the war many students in medicine have found it difficult to decide whether their duty to their country required that they enter the combatant ranks or complete their medical course so as to fit themselves to give more efficient service as fully qualified doctors. A large number of such students attached themselves to the various ambulance corps, and the fourth and fifth-year men were subsequently sent back to Canada to finish their medical course. The government has now arranged that first-year students of medicine, dentistry, or veterinary science, are to be called to the colors under the selective draft if physically fit. All other students of these subjects are to continue their studies, and are to form reserve corps to be called upon in case of military necessity. Upon graduation, if physically fit, these students will be given the military training necessary to fit them to accept commissions in the Army Medical Corps; and should they already have taken this military training they will be given leave of absence until called to the colors.

2. The Treatment of Eczema in Childhood.—Charles J. White finds that at the end of three years of concentration on the subject of eczema and of working and pondering over one positive and two possible accessories to our therapeutic armamentarium, he feels justified in making the following deductions: (1) There are two great types of eczema,—those curable in the hands of an expert and those which resist even the most scientific care. These two classes cannot be distinguished objectively. (2) Crude coal tar when properly used is curative in the majority of instances of moist eczema, and has proved of inestimable value. (3) There is no doubt that eczematous individuals, both young and old, react positively in decided numbers to the food tests and stool examinations—in fact he and his co-workers have seen among the children described in this communication 66 per cent. of positive food tests and 81 per cent. of abnormal stools. Therefore, they do not hesitate to say that food plays some rôle in the abnormal composition of individuals afflicted with chronic, rebellious eczema. (4) Proper feeding, as indicated by food tests and stool examinations, is capable in very young children (who eat elemental food), of producing a cure or of paving the way for a cure in a decided majority of cases. (5) In older children and in adult life the same successful results have been obtained only in a small minority of the cases; but it is possible that this failure is due less to the value of this same knowledge than to the fact that the food of this class of patients is practically always a complex substance and hence incapable of such scientific and exact preparation as is possible in the comparatively simple modification of milk. Until, therefore, it is possible by means of special diet kitchens to synthesize the food of older children and adults, we cannot hope to make use of these two modern therapeutic adjuncts in our fight against unamenable eczema. Certain eczemas not amenable to treatment were tested for food reactions, the following foods having been employed in the tests: Beans, wheat, barley, rice, oats, rye, lentil, corn, buckwheat, barley, pea, turnip, cabbage, carrot, strawberry, egg white, lactal albumin, beef, lamb, pork, and chicken. Various degrees of response to one or more of these foods was obtained.

5. Body Flexibility.—Stewart Lewis advises the systematic use of certain types of exercises for the production of body flexibility for the relief of impaired function, lowered resistance, and local and general disorders due to relaxed muscular condition and also to the opposite condition stiffness due to habit or nonuse. He says that extending a motion as far as we can we frequently find it limited by a tight band, the opposing muscle. Attempting to stretch this by steady pull, intermittent pull, or massage, we seldom succeed, in fact we may actually stimulate the muscle to increased contraction. *If, however, we keep up steady tension and sway the muscle back and forth we note a fine and then a coarser crackling sensation and the resistance yields.* Almost every one of us has a "weak spot" somewhere, some part of the body which tends to trouble us, especially when we are a bit tired, by a feeling of disagreeable tightness, pressure, even pain. Such dif-

ficulties may be greatly relieved by proper exercise of the part, preferably the entire body, to restore flexibility, muscle balance, and tone; neglected, they may go on to serious disorders. The following set of exercises are offered, especially for those approaching middle age who are decidedly in need of more body flexibility: *Head and neck.*—These exercises are especially helpful for the tired head and stiff neck of the brain worker or the nerve wearied person. 1. Force the head as far back as possible, looking upward. Force head as far to the left as possible, all the time trying to force it farther back. Move the head to right. Repeat five times and return to normal position. 2. Force head as far as possible toward left shoulder. Swing head as far forward as possible, all the time reaching toward left shoulder. Swing the head back as above. Repeat five times and return to normal position. Note the tightness of opposite side of neck, followed by crackling and relief. 3. Head right—opposite of above. *Trunk.*—Position, body erect, head back, chest up. Hands on hips, thumbs to rear. 4. This exercise is especially helpful for bad posture and for tired and sensitive back of the nerve tired. Lean as far backward as possible. Keep abdomen in. Swing as far to left as possible but forcing backward. Do not bend knees. Keep heels on ground. As you bend to one side raise opposite elbow as far as possible, to get pull of latissimus on spine. Bend to the right. Repeat five times and return to erect position. 5. Bend as far as possible to the left. Raise left elbow. Front. Back. 6. Bend right, then same as above. Front bending exercise on same principle may be used, but very little in cases of bad posture. *Shoulder.*—7. Swing arms in half or full circle, stretching shoulder muscles all you can. *Lumbar and thigh.*—This exercise is for selected cases of static backache and sacroiliac strain and is not used in regular drill. 8. Lie on table or high bed, body below hips hanging over the side. Swing legs both together, left and right. *Leg and foot.*—This is especially useful for prevention and cure of flat foot. 9. Stand erect, rise on tiptoes and sink as usually prescribed but with this modification: Stand pigeon toed and as you exercise try to force the toes more and more inward and heels outward. Be sure to rise just as high as you possibly can. In many cases of the class referred to the condition may have progressed beyond stiffness to actual tenderness and pain. It is difficult to decide whether one may exercise in such a case. He can only suggest that one proceed cautiously. Sometimes by experiment we find an exercise which gives grateful relief, as in tenderness at one point near a joint it may prove very helpful to stretch the muscles on the opposite side, thus relieving tension. If good judgment is shown in removing causes, such as overwork, bad nervous habits, etc., the relief afforded by these exercises is permanent. Better results will often be obtained if the patient is not only carefully instructed but the movement assisted manually, and the use of a considerable degree of force is sometimes permissible. A slight sprain may occur but requires only a day or two of rest.

7. The Disinfection of Pneumococcus Carriers.—

John A. Kolmer and Edward Steinfield point out that recent studies by various experimenters on the epidemiology of lobar pneumonia show that in a considerable proportion of cases this disease arises by infection from without, because of the entrance into the upper air passages of virulent pneumococci of the fixed serologic types, contracted from persons suffering from lobar pneumonia or convalescent from this infection. In studies of a large number of healthy persons in contact with cases of lobar pneumonia due to Type I or Type II pneumococci, four investigators report that about 12 per cent. were found to carry the corresponding types of pneumococci, whereas among healthy persons not in contact with cases of lobar pneumonia, these types were found in but 0.3 per cent. or less. In almost every instance the observers found that the type of pneumococcus in the carrier corresponded with that of the case with which there had been an association. Advisability, therefore, for the destruction of the pneumococci in the mouth secretions seems indicated. Kolmer and Steinfield offer as the results of their laboratory experiments in this direction the following solutions: 1:10,000 dilutions of ethylhydrocuprein hydrochloride or quinine bisulphate, quinine hydrobromide, and other eichinichs in a 1:10 dilution of liquor thymolis, constitute mixtures that may be readily used by persons as mouth washes and gargles. The slightly bitter taste remaining after the use of any of these washes is readily removed by rinsing the mouth with plain water. The systematic use of 1:10,000 solution of ethylhydrocuprein hydrochloride in 1:10 dilution of liquor thymolis twice or more daily may go a long way toward the protection of others if used by both patients of lobar pneumonia and those coming in contact with them often. The other above-mentioned drugs, while not quite as efficacious, are beneficial as substitutes. Similar dilutions in undiluted Dobell's solution may be used for douching or spraying the nose, or, incorporated in a dental cream, for cleansing the teeth. For washing the mouth and gargling, a solution is conveniently prepared after the following formula: Ethylhydrocuprein or quinine bisulphate 0.005, liquor thymolis 5.0, distilled water sufficient to make 50.0.

3. The Use of the Turbinals and Septum in the Repair of Injuries and Defects of the Wall of the Nasal Cavity. G. Secombe Hett.

1. A Discussion on the Surgery of Exophthalmic Goiter.—T. P. Dunhill considers that surgeons, as well as physicians, recognize that the removal of a large portion of a gland which is so essential to the bodily well-being as is the thyroid is a confession that the origin of its disturbances has not yet been discovered. But while recognizing this, they maintain that the manifestations of Graves' disease are the manifestations of excessive and disordered functional activity of the thyroid gland. Working on this hypothesis, they believe that, when other means have failed, sufficient gland tissue may be removed to place the patient on a greatly improved plane of health, while still leaving ample for physiological purposes. Referring to his own experience with reference to operation for this condition, Dunhill says that he has always found that removal of one lobe and the isthmus gives improvement which is readily recognized by both patient and observer. The removal of rather more than half the remaining lobe almost always places a patient on a plane of health which enables her to work and play and to feel well whilst doing so. Occasionally a third operation is necessary, and when necessary it is generally because one has not been able to decide how much was left at the second operation. The reason for this non-decision is because the portion to be left is never dislodged. Dunhill does not say that every case should be operated upon, and he is far from saying that every case should be operated upon at once or even early. But he desires to point out what can be done and how it can be done with reasonable safety. If in the case of a person severely ill with Graves' disease the state

of the thyroid were hyposecretion the removal of three-fourths of the gland should cause myxedema at once, and fairly constant. Yet, it never does, either immediately or later. On the contrary, the loss of psychical unrest and a condition of well-being obtains, which, before operation, was foreign to the patient. Dunhill cites several cases as illustrations of results he has obtained through operation. The following case shows the need of removing sufficient gland tissue. Miss M. was a healthy girl in the early twenties, when she developed exophthalmic goitre. The goitre, the prominence of the eyes, the tremor, the rapid pulse and the palpitation, were all characteristic. The first operation was one of the first six that Dunhill performed for this disease (1906). Consequently he removed only one lobe. She was improved, but remained far from well. This was the first case which compelled him to recognize that removal of one lobe was not going to cure, and he removed a part of the second lobe. After the second operation she lived a fairly active life, but she still had a large piece of gland tissue remaining in the region of the upper pole of the left lobe and was not free from tremor and palpitation. Her eyes had become practically normal after the second operation. He decided to remove still some more. This he did, and within a few days she felt quite a different being. Her eyes are now normal, her pulse is normal, she has no tremor and no palpitation. She has undertaken a tour on foot, lasting five days, over mountains, carrying a knapsack, and sleeping at nights in ordinary accommodation houses. She plays tennis regularly and is quite well. This was not due to rest in bed or medical treatment. Each time she entered hospital the night before the day of operation. As soon as sufficient gland tissue was removed she was completely better. Ten years later her health is normal. She is a vigorous woman.

3. Gastrointestinal Sepsis a Cause of Ménière's Symptoms.—T. Mark Hovell considers that although aural surgeons of late years have clearly drawn the distinction between Ménière's disease, or the class of cases to which Ménière referred in his paper, occurring suddenly in patients without previous ear trouble, and Ménière's symptom complex occurring in patients suffering from an affection of the middle ear—which condition for many years he has preferred to call by the simpler term of Ménière's symptoms—the distinction is not as yet universally understood in the profession, and there is in consequence a tendency, except with aurists, for any patient suffering from the group of symptoms which Ménière described to be regarded as having an incurable ear disease, so that palliative treatment is all that is possible. It is not his intention now to deal with the cases in which the symptoms are produced by syringing the ear when perforation of the drumhead exists, or by quickly rotating the patient, or to an extension of suppuration to the labyrinth, or are found in the course of an acute disease from inflammation or infective processes extending to it, or with the attacks of giddiness and tinnitus which occur sometimes as part of the vasomotor disturbances which accompany the menopause, or any of the cases in which the cause is obvious, but to confine himself to those which occur in patients suffering from middle-ear disease and come on without the reason being apparent. The treatment adopted not only greatly diminished the frequency and severity of the attacks, but in some cases practically freed the patients from this distress-

ing condition. In many of the patients the following conditions obtained at the first visit: A furred tongue, congested pharynx, nasopharyngeal catarrh, hypertrophic rhinitis, flatulence frequently causing much distension, and constipation, although sometimes the motions were broken and light colored. Several patients stated that previous to an attack the motions have been noticed to be especially offensive. With these symptoms the blood pressure was often high, for Hovell states that with toxemia due to intestinal sepsis this last symptom is a common result, and some dilatation of the heart existed in many cases. Pathological mouth conditions as well as other conditions may produce this result also. With the patient suffering from the above symptoms, it is not surprising that closure of the Eustachian tubes is usually present when Ménière's symptoms exist, for gastrointestinal derangement is a common cause of congestion of the pharynx and nasopharyngeal catarrh and consequent closure and catarrh of the Eustachian tubes. Nor is it to be wondered that tinnitus and giddiness are found when toxemia is present, these symptoms being more the result of this condition than caused by the high blood pressure when it exists. With these conditions present gastrointestinal antiseptics are in order, as well as medicines for the reduction of blood pressure, and also a preliminary measure of washing out the stomach with an alkaline solution. In some cases Hovell has obtained a specimen from the stomach during fasting and has had a vaccine prepared and administered as an adjunct to other treatment. For the reduction of the blood pressure he advocates three to five drops of a solution of adrenalin chloride with a little dilute hydrochloric acid, rightly flavored, for each dose; but this is only an adjunct to the intestinal clearing out, for which he first administers a full dose of castor oil. Combined with this, local treatment of the Eustachian tubes brings about a normal condition. For this he employs an injection into the tubes through a catheter of a few drops of collosol argentum. The nozzle of the syringe which injects the drug into the catheter must not fit the catheter tightly, or the drug might be forced directly into the Eustachian tube instead of being sent into it in the form of a spray by air pumped from an air-bag, the nozzle of which closely fits the catheter. To lessen the nasopharyngeal catarrh, collosol argentum or collosol iodine sprayed directly backward through the nostrils so that it reaches the nasopharynx and the orifices of the Eustachian tubes is a beneficial measure. This entire method often relieves tinnitus of long standing from other causes. Collosol argentum, Hovell also states, is useful for stopping earache, and he applies it by placing the patient with the meatus of the affected ear upward and then filling the canal with the drug and allowing it to remain there.

Le Progrès Médical.

December 1, 1917.

Pseudomalarial Septicemia, Cause Unknown, with Meningococcus Meningitis.—Challamel reports a rare disease association in a soldier of 19 years. The admission symptoms were fever and erythema nodosum on all four extremities. For 10 days there was a peculiar type of remittent fever nonresponsive to quinine with a maximum of 103° F. The patient was otherwise normal—ate, drank, conversed, read. In other words, there was notable dissociation in the picture. As no organic affection could be located a provisional diagnosis was made of sepsis and an intravenous injection of colloidal silver brought the temperature to normal, where it remained for 24 hours. Upon its reascension there were associated violent arthralgias which were in harmony with the erythema nodosum, now paling. Sodium salicylate gave relief to the pains. The fever curve now assumed the "needle" type. A fresh examination revealed absence of local lesions and several blood tests were negative. A few days later the fever assumed a frankly malarial type—severe chills, high temperature and profuse sweating. The range of temperature was 36°-41° C. During all this time the patient seemed well, would not remain in bed, came and went at pleasure. There was no history of malaria and intramuscular injections of quinine were inert. Nine days after the supervention of the malarial type of fever the picture changed sud-

denly to that of meningitis. Lumbar puncture gave exit to a purulent fluid under pressure. Death occurred on the twelfth day of meningitis in coma. Blood cultures were negative as before. From the spinal punctate a coccus was found of the meningococcus type which did not cultivate. The author chooses to be a unicist in explaining this case. As no cause was found for the sepsis, he decides that it is simpler to ascribe it to the meningococcus than to regard the latter as the cause of a secondary infection. Cases have been reported in which a meningococcemia terminated after some weeks in a meningitis. In the author's patient failure to find a diplococcus in the blood must be ascribed to defective technic. In meningococcemia without meningitis we may see an exanthem suggesting ordinary erythema nodosum, joint pains, a malarial type of fever and enlarged spleen. It is possible that early lumbar puncture would have revealed latent meningitis, in which case serotherapy might have saved life. The single intraspinal injection of polyvalent antimeningococcus serum received by the author's patient did not in the least modify the course of the disease.

Hygeia.

October 16, 1917.

History of Eustachian Catheterization.—Key-Aberg calls attention to the work of Archibald Cleland, an old English regimental surgeon who recommended an inflation at a time when liquid injections were universally practised. His pioneer efforts were virtually ignored and not until nearly a century had expired did his method come into general use. Cleland's original paper was published in the *Philosophical Transactions*, London, 1741, and the title conveys no suggestion of the method in question. Among various aural apparatus described is a Eustachian catheter. Cleland's immediate followers in the use of the latter included Petit, Douglas and Wathen, the latter publishing numerous cases in the *Philosophical Transactions* for 1754. In 1821 Itard and in 1827 Deleau revived the resource, and in the fulness of time the pioneers of modern otology—men like Tröltzsch and Politzer—gave the method its full due.

Berliner klinische Wochenschrift.

October 22, 1917.

The Surgical Treatment of Facial Paralysis.—A. Kochmann offers us a general review of this subject. He considers somewhat lengthily the various procedures which have been resorted to with the prospect of restoring the functions of the injured nerve and gives the literature of the most recent publications on the question. After the first essays of anastomosis between the peripheral end of the facial with the spinal or the hypoglossus (the latter procedure having given the best results), with Busch appeared the technique having for end an entirely cosmetic result, obtained by the use of loops of iron wire, which, by fixing the angle of the mouth to the malar bone, raised its angle. However, the best results seem to be promised by Gersung's procedure, in which the paralyzed muscles of mimic are united to those muscles which have maintained their physiological functions. In certain cases this method may bring back a considerable mobility of the face. Now, although Gersung has sought for the tutor muscle in the domain of the intact facial branches, Rosenthal has sought for it in the muscles of mastication. Nevertheless, this procedure will not result in a return of the mimic muscular play to the same extent as that obtained by Gersung's technique, in the opinion of Kochmann.

The Intravenous Injection of Urated Calcium Chloride.—C. Wiénand-Rose has experimented with the above named product upon himself and considers it less irritating than other calcium salts. He injected a 10 per cent. watery solution in the dose of 10 c.c. The therapeutic indications are as follows: Acute bronchial asthma, hay-fever, hypersensibility of the nasal mucosa, and urticaria; they are to be given also at the time seric injections are exhibited, in order to obviate anaphylactic phenomena.

Münchener medizinische Wochenschrift.

October 23, 1917.

Spring Plaster Casts for Preventing Deformities Due to Paralysis of the Peroneal Nerve.—H. Lehr has noted that the time elapsing between the receipt of the lesion and that of the nerve suture, which is necessitated by the treatment of the wound itself, as well as the complications arising, is frequently the cause of ultimate deformity which prevents *restitutio ad integrum* of the functions of the limb involved. In order to do away with these untoward incidents, Lehr has had constructed plaster casts made in two parts, using very pliable wire as a framework. The two portions of the plaster splint are, consequently, movable over each other and therefore allow the patient to execute movements of flexion and extension. The circulation of the parts is favored in the limb and tardy trophic disturbances do not occur.

The Influence of Balancing Movements on the Human Organism.—A. Ritschl remarks that, aside from the reactions of the nervous system, one should take into consideration more than is usually done certain mechanical influences, particularly the pressure exercised by fluids on the walls of the containers, as for example the heart, stomach, meninges, etc.

Deutsche medizinische Wochenschrift.

October 25, 1917.

Treatment of Malaria with Methylene Blue and Salvarsan.—L. Appel considers the treatment of malarial infection by successive injections of the above named drugs, which he believes exercise a favorable action on the morbid process. Appel thinks that the dye acts electively upon the specific organism, while, under the action of salvarsan, the transformation into toxic products gives results which may realize the sterilization of the host. A similar idea occurred to Roosen, who has treated septic conditions with methylene blue combined with calomel (*Deutsche medizinische Wochenschrift*, No. 10, 1914). The technique is as follows: A 2 per cent. solution of chemically pure methylene blue is injected intravenously in the dose of 10 c.c. Four hours later a similar injection of neosalvarsan (45 centigrams in 10 c.c. water) is given. These injections are repeated on the tenth and twentieth days. In cases where this treatment is not followed by success the injections are continued once weekly until the fever has entirely disappeared.

Dysentery.—Czaplewski has noted that the usual etiological factors of dysentery (*bacillus* of Shiga, Flexner's γ *bacillus*) are usually found wanting. On the other hand, the epidemic of dysentery studied by the writer was characterized by an acidopoiëtic encapsulated bacillus, which was found both pathogenic and violently toxic.

Diagnosis of Intestinal Affections.—A. Alber comes to the conclusion that, as far as dysentery is concerned, bacteriology should give way to clinical symptomatology in making the diagnosis of the affection.

Wiener medizinische Wochenschrift.

October 27, 1917.

Treatment of Soldiers with Cardiac Affections in Sanatoria.—K. F. Wenckebach, speaking from a purely practical viewpoint, has come to the conclusion that it has become necessary to organize the treatment of the cardiopathies of war. A sojourn in a sanitary establishment acts by withdrawing the patient from his mental preoccupations and activities by directing his thoughts in the sense of a punctual fulfillment of his medical prescriptions. After careful selection of cases which are undergoing hospital treatment (advanced cases of uncompensation), such patients placed in sanatoria can be benefited particularly by therapeutic exercises. The writer advises a mild mental activity, as much for producing a certain amount of cardiac exercise as for occupying the patient's mind and thus relieving him of psychic depression. The writer believes that hydrotherapy is too much neglected, particular favor being shown to treatment with carbonic acid gas baths. The hydrotherapeutic methods advantageously

take the place of the latter treatment in hypotonic states. The use of electricity has not given any marked results in cases treated by the writer. Carbonic gas baths may give real success on the condition that they are given to strictly selected cases, particularly in hypertensive states.

Scorbutus at the Front.—E. Schneider gives a description of cases under his observation since 1916. He has not been able to convince himself of the reality of epidemics in the strict sense of the word. He is more inclined to admit that changes undergone by foodstuffs and meat from cooking and also probably from fermentation give rise to the process.

Palpatory Determination of Maximum Pressures.—Baumann of Sahli's clinic concludes that he has refuted experimentally the assumption of von Benczler that the palpatory determination of maximum pressure only suppresses the peripheral pulse and not the circulation of the blood, so that the maximum pressure is found to be too low. On the contrary the persistence of the blood stream beneath the compressing cuff is connected with the persistence of the pulse—no pulse, no circulation. The fact that the pulse seems to return before the circulation is due purely to technical shortcomings in the experimentation. In the use of the cuff method the blood pressure may be altered as a result of reflex activities. While the disadvantages of a narrow cuff do not hold good for cuffs of average width, increase in width varies directly with defective lowering of figures as a result of dynamic loss of pressure. Hence published figures of maximum pressure possess no absolute value unless the width of the cuff has been taken into consideration. It therefore follows that the pelotte—of a diameter not exceeding 3 cm.—should be free from the objections which inhere in a wide cuff while it may also be shown that it is without the disadvantages of a narrow cuff. The method of the determination of the suppression of the radial pulse by the Riva-Rocci procedure is defective because with radial pulse suppressed the brachial pulse can still be felt. Errors as high as 20 mm. Hg. can be recorded as a result. To avoid this source of error the brachial pulse should be palpated beneath the cuff, a procedure impracticable in fat subjects. There are other sources of error not sufficiently regarded in connection with manufacturing defects in the various manometers. In this connection the writer praises the new apparatus of Sahli (1916 model), which is from 5 to 8 mm. more accurate than the older model.

Calcium and Phosphoric Acid Metabolism in a Case of Rachitis Tarda.—Ricklin (Professor Feer's clinic) relates a typical case of late rickets in a boy of 15 years. Two years before he had been sound like the other children (4) in the family. At this period he began to suffer increasingly from pains in the knees and ankles and developed a marked case of knock knees with great impairment of locomotion and psychic alteration. Anemia and tetany were both absent. The supposed causal factors of rickets were not in evidence. He had had plenty of fresh air and good food. Endocrine factors were therefore under suspicion but the good state of development of the genitals seemed to antagonize such a view. There was nothing to implicate the parathyroids. The treatment consisted at first of phosphorized codliver oil; later insoluble calcium phosphate was substituted for phosphorus. The calcium and phosphorus retention was shown to be better under the latter plan. Metabolism studies were abandoned after it had been deemed necessary to operate upon the knock knees. Radiograms of the wrist showed improvement in the diaphyses of the long bones and general texture of the osseous structures. The photograph taken before the discharge of the patient shows a well-developed and well-set-up boy, hardly recognizable in the photograph taken upon admission.

Pseudotabes and Meningism Following Diphtheria. Oppenheim and Haller report this sequence in an adult. Thus far it has been seen only in adults.—*La Presse Médicale*.

Book Reviews.

HELPING THE HELPLESS IN LOWER NEW YORK. By LUCY SEAMAN BAINBRIDGE, Honorary Superintendent Woman's Branch, New York City Mission Society; Author of "Round the World Letters." Introduction by Rev. A. F. SCHAUFLER, D.D. Price, \$1.00. New York: Fleming H. Revell Company, 1917.

IN no large city of the world, not even excepting London, is there such a cosmopolitan population as in the tenement district of New York. It undoubtedly contains the most teeming mass of all sorts and conditions of men and women that can be found anywhere. Poverty and disease stalk throughout the district, and it is in the best interests of Christianity, humanity, and public health that aid should be given to the sick and indigent. For a long time the New York City Mission has, through the agency of the noble band of men and women who have given their services, done much to relieve the sickness and distress, which not only hamper the activity of the sufferers but which menace the entire community. Among those who have been especially strenuous in this good work is Mrs. Lucy Seaman Bainbridge, who was for eighteen years an active member of the missionary staff.

In "Helping the Helpless" Mrs. Bainbridge has set down tales of some of the individual cases which came within her ken as a city missionary. These are dealt with from the moral and physical standpoints and provide true human documents which are, at the same time, poignant and instructive. It may be said truly that the book is valuable from both the social and medical points of view. The medical man is brought into contact with many of these down-and-outs who form the subjects of some of the stories, and any of us could certify to the correctness of the incidents, though few could tell the tales so illuminatingly and in such sympathetic language. The stories are all interesting and well worth reading, and they also serve to throw a light on the commendable work of the City Mission Society. The little book is dedicated to the author's son, who is Dr. William Seaman Bainbridge of this city.

PREVENTIVE MEDICINE AND HYGIENE. By MILTON J. ROSENAU, Professor of Preventive Medicine and Hygiene, Harvard; Director of the School for Health Officers of Harvard University and the Massachusetts Institute of Technology; formerly Director of the Hygienic Laboratory, U. S. Public Health Service, etc. With chapters on Sewage and Garbage by GEORGE C. WHIPPLE, Professor of Sanitary Engineering, Harvard; Vital Statistics, by JOHN W. TRASK, Assistant Surgeon General, U. S. Public Health Service; Mental Hygiene, by THOMAS W. SALMON, Medical Director, National Committee for Mental Hygiene, etc. Third edition. Containing a special section on Military Hygiene. Price, \$6.50. New York and London: D. Appleton and Company, 1917.

THE present edition of this now well-known book contains a valuable section on military hygiene. The fact that the author served for many years as an officer of the Public Health Service fully entitles him by virtue of much practical experience to write on this subject. He states in the preface that "this entire volume may be regarded as dealing with military hygiene, for the fundamental questions concerning food, water, soil, ventilation, vital statistics, disposal of wastes, disinfection, and the prevention of the communicable diseases are essentially the same for the soldier and the civilian." In this section such topics as the examination of recruits, organization of the medical department, the Red Cross, rations, equipment, diseases of the soldier, hygiene of the tropics and cold climates, are dealt with in a concise and authoritative way. A detailed reference list on these subjects is appended. That part of the book devoted to communicable diseases represents the latest word on all that pertains thereto. The chapters on sewage and refuse disposal, vital statistics and mental hygiene are written by men who are recognized as specialists in these lines.

The book as a whole is very complete and fully maintains the reputation established for it by the author in the previous editions. It is a text that is to be par-

ticularly recommended at the present time on account of the valuable information which it contains not only for the medical man already in service, but also for prospective army doctors. The publishers might have selected a better grade of paper commensurate with the value of the contents.

HYGIENE OF THE FACE AND COSMETIC GUIDE. By RICHARD W. MULLER, M.D. Price, \$2.00 net. New York: E. P. Dutton & Co., 1917.

IN the years past this subject has been delegated entirely too much to the inefficient hands of so-called beauty specialists, barbers, and quacks. That such an important and expressive part of the human anatomy as the face must need special care and attention in order to keep it in normal condition, and to preserve whatever beauty nature may have bestowed upon the individual, needs no further comment here. The fact which does need emphasizing, and strongly, is that this care and attention should be given under the direction of competent skin specialists and not allowed any longer to remain a field of remuneration for a horde of quacks.

Dr. Muller has gone a considerable distance along the right road in presenting this book to the public. He has graciously dedicated it to "The Queen of Her Sex the World Over, The American Lady," thus finding a sure, fair, and competent reading public.

The subject of facial conditions is taken up with reference to age, and treatment is offered accordingly. Prophylaxis and hygiene, together with scientifically prepared formulæ for cosmetics, also massage and other methods of rejuvenation are included.

What a boon to mankind it will be when more members of the medical profession awaken to a realization of the importance of this heretofore neglected branch of the medical art, and attempt, not to remake, but to improve upon what nature has been niggardly in bestowing of natural beauty in men and women, as well as preserving that most wonderful of all gifts, beauty of face in feature, texture of skin, and coloring.

MANMALIAN ANATOMY WITH SPECIAL REFERENCE TO THE CAT. By ALVIN DAVISON, Ph.D., Ex-Fellow of Princeton University; Professor of Biology in Lafayette College. Third edition revised by FRANK A. STROMSTEN, D.Sc. (Princeton), Assistant Professor of Animal Biology, State University of Iowa. With 115 illustrations, etc. Price, \$2. Philadelphia: P. Blakiston's Son & Co., 1917.

THE first edition of this work appeared in 1903 and was actually larger than the present volume, something rather unusual in bookmaking unless deliberately planned. A comparison shows that the introduction has been considerably shortened. Dr. Stromsten has also omitted the entire section on the fiber tracts of the spinal cord as belonging properly to a more advanced textbook. On the other hand, the section on the classification of animals has been expanded and radically changed. There is a new section on the skull as a whole, and the chapter on general structure has been rewritten.

AN INTERMEDIATE TEXTBOOK OF PHYSIOLOGICAL CHEMISTRY WITH EXPERIMENTS. By C. J. V. PETTIBONE, Ph.D., Assistant Professor of Physiological Chemistry, Medical School, University of Minnesota, Minneapolis. Price, \$2.50. St. Louis: C. V. Mosby Co., 1917.

IN the theoretical first portion the food substances are duly considered, and in this respect the volume suggests a book on dietetics, especially as chapters follow on the physiology of digestion. The section ends with a chapter on the urine. The laboratory section follows and duplicates the classification throughout. Whether such duplication is advisable will doubtless appear in time.

In the next edition the author may find it of advantage to have a single section, with the laboratory work appended to each chapter of theory, or to fuse the two elements into single chapters, or to make the work a laboratory book pure and simple. By the word "intermediate" in the title the author evidently understands a transition between ordinary descriptive text and laboratory manual of procedure. The volume is of the type which must be judged by its reception.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 13, 1917.

DR. ROGER H. DENNETT IN THE CHAIR.

New Plans for Health Centers.—Dr. HAVEN EMERSON, Commissioner of Health of New York City, said that he had been asked to make a brief statement of the object and principles of the new plans for the establishment of health centers. Any one who attempted to analyze the results of health organization as set forth in the reports of the Bureaus of the Department of Health would be struck by the fact that no officer of the Department was familiar with all the needs and phases of civic health work in any given borough or district of the city. The general death rate, the infant mortality rate, the rates of incidence of the different communicable diseases in the community as a whole, were known to the Health Department, but as soon as one came to analyze these rates he found that he was dealing with too large groups to make these statistics applicable to any one district. The attempt had been made to analyze these statistics so that they could be applied to local racial groups, to industrial groups, or to areas where especially favorable or unfavorable sanitary conditions prevailed, and the results had not been satisfactory. For many years the system of administration of the Health Department had been the growth of a series of kingdoms, within an empire, each to a great extent independent and with its functions and sphere of influence sharply defined; each bureau was served by a staff of employees more or less specially trained and independent of the other bureaus, in thought, action, and method of work. There was no opportunity or desire for conference or comparison of the records and results or for consultation for the sake of obtaining joint action between the different bureaus. There was no place in the city where investigation was being carried on in respect to the effectiveness of the existing or other possibly desirable methods of health administration. The advisability of carrying out such an experiment was evident, and it had been carried out in Federal Census unit, No. 6, in Manhattan. The records for this district, in Manhattan, were available for 1900, 1910, and for the succeeding years. This area had been utilized as an experiment station, where different methods of serving the functions of the four field bureaus, namely, those of Preventable Diseases, Child Hygiene, Food and Drugs, and the Sanitary Bureau, had been tried out and the results studied under one directing officer. The health officer of this district was expected to know everything regarding environment and its results, the occupations and the results of occupation of the residents of the district, everything about the food supply, the causes and incidence of sickness and death in this area, and the methods of approaching the groups of people living and working in these city blocks, in order that the Health Department might render the most effective service to them. The results in this district made it seem advisable to try out the system in a larger group of people in a growing community with a more varied population. The Borough of Queens seemed to fulfill the conditions suitable for such an experiment. The plan as applied there comprised briefly a sharp cut line and staff organization. The population of this borough was about 400,000, and it was divided into four districts of approximately 100,000 people each. At the head of each district was placed a physician trained in the work of some one or more of the four field bureaus. In each Health District there was a headquarters and one person was placed in charge, whose business it was to become familiar with every detail of the conditions in that community with which the Department of Health should properly have an interest. This physician was on hand to meet the public, and he studied and learned that particular community. The various functions of the Health Department were administered through this central district office, where a physician, adequately trained in infant welfare, school medical inspection work, in tu-

berculosis work and in the diagnosis of communicable diseases was in charge, or if all these functions were not covered by one physician, others attached as part time medical inspectors were on hand to assist and supplement the work of the health officer. The nurses were also trained in their visiting to fulfill all district nursing functions of the Department and to keep their eyes open for all matters that might come within the province of the Health Department. In short, the effort was to get away from specialization of service and to obtain a more intensive application of all the functions in smaller groups of families, or tenements, or factories, by a field force adequately trained and directed in routine field procedures of each of the four bureaus. The results from the point of view of preventable diseases, the welfare of infants, the inspection of school children, and the work in tuberculosis was as good if not better than before the district system was introduced, and where any difference in the results between the two systems was apparent the result was in favor of the district system. Under the district system the community felt that it had something definite, something that was its own, instead of feeling that the activities of the Health Department, as administered from a Central Bureau in another borough, were intangible, impersonal, and indefinite. Another point in favor of the district system was the opportunity it afforded for the focusing of volunteer work of physicians and relief agencies in such an area. As an instance of this, in the Borough of Queens before the introduction of the district system there was no venereal clinic, no orthopedic clinic, no eye clinic. There was a population of 400,000 people without these indispensable special services. The physicians practising in these communities knew the need for this special service, and were willing to volunteer their services in such local centers as the district and health office now offered. A beginning had now been made, and several special clinics had been established in Queens. The reports that came in from these district health officers were radically different in their point of view from those received from the borough officers in other boroughs. One was struck with the intimate sense of responsibility, and with the all-embracing human interest in each aspect of the lives of the people shown by these district officers. The physician in making a diagnosis of the individual might need the assistance of the specialists, so the man in charge of the health center submitted his data to the staff officers as consultants. These staff officers were the specialists or experts, the directors and division chiefs of the various bureaus, and under the district system were just as responsible as under the bureau system, but instead of working through specialized bureau employees responsible only to them, they were studying results and making recommendations to physicians, the health officers, who were responsible to the Health Department as a whole through the assistant sanitary superintendent of the borough, and through him to the Commissioner. It had just been planned to extend this system to Brooklyn, in 1918, and the budget for the coming year had made provision for this. There should be fourteen such districts in Brooklyn, but the probability was that only three would be established at first and the system gradually extended. The difficulty had been to go slowly enough to consolidate the work properly and have it sufficiently well organized to stand in competition with the well-established bureau type of work. The cost of the two systems was about the same, but with some economies in rentals, janitor service, and equipment, under the district system. There should be in every community a social, educational, and recreation center, preferably conducted in relation with a school, and there should also be voluntary cooperation between physicians of the locality for a pay diagnostic and therapeutic clinic. These two facilities, together with a health district service such as was outlined, should produce tangible results in the improvement of the health of all within reach.

Dr. L. E. LA FETRA said that all who had listened to this admirable presentation of the health center plan must feel that it marked an epoch with regard to our methods of health administration, and that we had made a great step forward because we had taken a

step back to the community idea in which all health problems by one man or a small group of workers. This was a method of administration by which the community spirit could be aroused and developed. The group system of administration had long been employed in Paris. Paris was divided into *arrondissements*, or small departments, from which all public health activities radiated, and each department took great pride in its *mairie* and its achievements. London was administered in the same way, and one found a great deal of community spirit in these groups. Dr. Emerson had pointed out the advantages of the broadened view resulting from this plan of coordinating the work of the different bureaus, but it seemed to the speaker that he did not make enough of the advantage of having one nurse take up all the problems of the family. There was a great deal of complaint among tenement house mothers because of visits from so many nurses, each coming for a different purpose. One nurse ought to be able to perform the functions now distributed among several if she had the proper spirit. It might be well in developing this system to go slowly, especially in view of the difficulty that was likely to be encountered in getting the proper personnel for the carrying out of this plan, though undoubtedly men and women could be trained for this work. In summing up, Dr. La Fetra said he failed to see any adequate objection to this plan, and he congratulated the city on having Dr. Emerson to elaborate and undertake its practical application.

Dr. SIMON TANNENBAUM said he was in entire accord with the Health Commissioner on Health Center organization. The Health Center system was organized on three basic principles. 1. Prevention of Overlapping. 2. Local administration in accordance with local needs. 3. Development of the community spirit. 1. *The Prevention of Overlapping.*—This could best be illustrated by explaining the difference between the bureau and the health district systems. At the present time each bureau had its own force of employees who worked independently of each other. The employees of the bureaus were again subdivided into divisions, each division having its own set of employees working independently of other divisions. As an illustration, there was the Division of School Medical Inspection, the employees of which did nothing but perform that particular work. A nurse of that division would visit a home for a physical defect and, owing to her status as a school nurse, she would not be able to take any cognizance, for instance, of a case of tuberculosis in the family. The same was true of Baby Welfare nurses, of the nurses visiting midwives and foundlings, of the tuberculosis nurse, and the contagious disease nurse. Under the health district system the family had at last come into its own. It was treated as the basic unit for health department service; one nurse visited the family and served all the Health Department functions to the family and was better able to minister to them than four individual nurses, who could not see the entire needs of the family for Health Department service. It was during the health district system that the Family Record Card came into existence; this was a continuous record of the family, as far as service rendered by the Health Department to the different members of the family was concerned. This was never thought of and in fact was impossible under any other system. It was true that an all round nurse and an all round medical inspector did away with specializing, but that they considered an advantage rather than a fault, because, first of all, there were no real specialists in the Department. In the second place they were unwilling to admit that a nurse should visit foundlings only, or babies attending welfare stations only, or babies suffering from physical defects only, or children suffering from contagious diseases only, and that as soon as she attempted to perform two functions her worth was greatly impaired. The same was true of medical inspectors. Besides there was a great saving of time in the obviation of overlapping, which had increased the output of work and reduced the *per capita* cost of functions so that they could now perform more work with the same number of employees or the same work with fewer employees. Figures showed that the value of preventive work had been increased on account of the

prevention of overlapping and the coordination of functions. 2. *Local Administration.*—While New York was thought of as a unit of 5,000,000 inhabitants, it must not be forgotten that it is a cosmopolitan city, consisting of numerous races, which had clung to their own racial characteristics, and Health Department administration that might apply to one race would not apply to another. It was impossible for an administration controlled from headquarters to take cognizance of these different characteristics. It was only the man on the spot who was familiar with the conditions of the district who was really able to handle them successfully. The speaker described the work that had been done in the Borough of Queens through the coordination of functions and as an instance cited that during the present year all pre-school examinations had been made in Greater New York for the first nine months, while about 100 were made in the Borough of Queens alone. 3. *Development of the Community Spirit.*—This basic principle was even more important in the conservation of the health of children than the other two enumerated. The conservation of the health of children was not a medical problem only, but was a social problem to perhaps a greater degree and in order to look at it from that point of view the spirit of the community for the purpose of social and medical cooperation with the Health Department must be aroused. While this could be done theoretically under the bureau system, it was a fact that it had not been done as well, and that the health district organization had shown the way in which it could be accomplished. The speaker quoted from the report of the Committee of Public Health of the New York Academy of Medicine showing the advantages they had found in their investigation of this system. He said that after all the infant mortality was the real index of the work done among children and they could point with pride to the record in the Health District organization. In the Borough of Queens, in 1915, before health districts were organized, the infant mortality rate was 102. In 1916, when the health districts were organized in that borough, it was reduced to 93, and in the present year, up to the present time, it had been reduced to 91. In Health District, No. 1, it had been reduced to 70 in 1916.

Dr. EMERSON in closing, stated that it was well known that the infant mortality, was a fair guide to the sanitary progress of a community, but under the bureau system only the mortality rates by boroughs were kept and as had already been pointed out, if one applied the rates for the city or a borough as a whole to a particular district one might expect to make mistakes. One could not take the decrease in the infant mortality as a valid argument without reservations. A factor that must be recognized was that the health of a community under this plan depended upon the quality and qualifications of the health officer in charge of the center. The health officer in charge of a center received \$3,000 a year for full time service and must abandon his private practice, or any demand upon his time which would prevent his responding to a call from the Department at any time, day or night. It was difficult to get capable men who were willing to abandon their private practice, especially with the slight prospect of advancement. One of the advantages of the district system was that it made it possible to get different groups of men together for instruction, as janitors, food handlers, employers, etc. This giving of instruction to certain groups of people had been shown to be very effective.

The National Danger from Defective Development of Growing Children in Time of War.—Dr. HENRY DWIGHT CHAPIN presented this paper (see page 89).

Dr. S. JOSEPHINE BAKER emphasized the grave importance of the question of undernourishment in children. For the past two years they had known that conditions in this regard had been increasing and for a year and a half they had been trying to bring the matter to the attention of the public. In 1914, their statistics showed that 5 per cent. of the children in the public schools of New York were suffering from malnutrition; in 1915, this had risen to 6 per cent. and in the school year 1916-17 it had risen to 12 per cent. These figures were sent in by the medical inspectors in their ordinary line of duty. In order to ascertain

whether or not there was any basis of error, Dr. Willis, Chief of the Division of School Inspection, and the speaker had undertaken an investigation. Their cases were all tabulated according to the Denfermline scale. They found that some of their doctors had become so accustomed to seeing undernourished children that they considered undernourishment as a racial or local type and in applying the Dunfermline scale they had taken children of certain localities and grouped them into four classes, making their diagnosis relative rather than absolute. They knew that they were doing this, but stated that all the children of certain neighborhoods showed a condition of undernourishment and therefore they felt that the condition of undernourishment was so universal that they had simply graded degrees of actual undernourishment as there were no children to be placed in No. 1 group. These figures, as well as those of Dr. Chapin, showed that undernourishment among the children of this city was critical. The statement should be made, however, that malnutrition was not the result of actual starvation. The children did get food, but the condition was the result of wrong feeding and long continued underfeeding. While it was true that there had never been so little unemployment and wages had never been at so high a level as they were at the present time, the increase in wages had not kept pace with the buying power of a dollar, particularly as far as food was concerned. Where the food supply of a family was curtailed the child was the first to suffer, because he needed food for growth as well as for the replacement of bodily waste. The adult might stand a restricted diet fairly well; the child was almost always permanently impaired. Dr. Baker referred to the experience of the belligerent countries in having neglected relief work among infants and children during the first year of the war. When the governments realized the effect of this neglect they immediately took steps to remedy the mistake. Dr. Baker also called attention to the report of Dr. Lucas, in connection with his work in Belgium, stating that he found tuberculosis on the increase among the children and he traced this increase directly to undernourishment. After canteens were established for children in Belgium, the incidence of tuberculosis was much decreased. We must realize that undernourishment in children means lowered resistance and that continued undernourishment would have a permanent effect upon the development of these children. We must expect to have a marked increase in the incidence of tuberculosis in this country unless the problem of undernutrition in our younger age groups was given immediate attention. Dr. Baker related her experience in investigating small groups of children, a short time ago, in an effort to find out what they were eating. The investigation seemed to show that there was a marked relation between malnutrition and the food these children were receiving. We must remember, however, that malnutrition was a very complicated entity not dependent upon feeding alone, but upon environmental conditions as well. In order to attack the problem from all sides one would have to readjust the entire social structure. It seemed at the present time that the most direct way was to feed these children; they were not getting enough of the right kind of food. Their daily routine consisted usually of coffee or tea and bread for breakfast, with a quick lunch of ice cream, pie, cake, or something equally indigestible, at noon, and at night a late, hurried, and unsuitable dinner. They knew that the provision of adequate school lunches had a practical, definite effect upon the health of the children. Their problem was how to make the school lunches available by extension of the machinery already in existence. It had been said that the children did not like the type of food served, and that they would not eat cereal and would not drink milk. That was true, at first, but they had found that after instruction and proper supervision by the nurse, they not only ate it but their mothers showed a distinct willingness to find out how the cereal could best be cooked and to give the children the food they needed. The feeding of these children without any question of charity but simply as a matter of common justice was a duty of this country at the present time.

Dr. CHARLES HENDEE SMITH agreed with the previous speakers as to the seriousness of malnutrition. In attacking the problem people would have to be educated to the fact that the thin child was not a healthy child.

Thinness was not natural to a child. The thin child had less resistance to disease as a rule and less reserve fat to fall back upon when he was ill than a well nourished one. He was constantly kept back by the loss of weight incident to heavy illness, so that he was always behind, gaining less than he should. A child of this sort fell an easy prey to acute illness, and as he grew up was very apt to acquire tuberculosis. Dr. Smith reviewed the various causes of malnutrition—diseases and defects—and said that the great majority of undernourished children were simply showing the results of bad habits of life. Their lives were at fault in so many respects that it was difficult to know where to begin to correct them. He illustrated this by giving a sample day from the life of a child among the poor. It was perfectly evident that no child could gain on such a regime in which practically every single phase of the daily life was at fault. It had been shown that it was possible to make a thin and weak child grow fat and strong if no serious disease were present and if the daily life of the child could be controlled. The men in the medical profession had been doing this with their private patients for years. Nothing repaid effort so wonderfully as the results obtained in this kind of child. The last few years had seen a number of attempts to apply more widely the principles which were known to be successful in individual private patients and in controlled groups of children. The class plan of treatment was the way in which this could be most easily accomplished. Such a class had been conducted by Dr. Emerson in Boston for some years and one had been in existence at the Bellevue Hospital Out-patient Department for over a year. There were several others in the city. They found that class talks to the mothers and to the children saved time and often made a deeper impression than did the same advice when given to individuals. Lectures on foods, cooking, and on the advisability of eating slowly, the necessity of rest, fresh air, exercise, and cleanliness were given at frequent intervals. Food exhibits and printed diet lists were used freely. The children were spurred to try to gain weight by the spirit of competition with each other and by working for prizes. A visiting nurse followed up the children to the homes and collected information which often brought out the cause of the child's malnutrition. It had been found that over two-thirds of the children could be made to gain at two or three times the expected rate for their ages. The one-third of the children who gained at the average rate or less were failures because of extreme poverty, lack of cooperation, ignorance of parents, or some one of the diseases, such as tuberculosis. In the endeavor to solve the problem of malnutrition a broad educational campaign must be the main reliance. The people must be taught to think about their food and the expenditure of their money by somewhat the same means as they had been urged to buy Liberty Bonds. Nutrition classes should be established in all of the out-patient departments of the city, and parents must be educated to take heed of the weight of their children and to take every child to a doctor or a dispensary if his weight was below the average, or if he did not gain at the average annual rate for his age. School lunches should be extended so that every child who could not get decent lunch at home could have the opportunity to get a nourishing midday meal at a nominal cost. Such lunches should be really nourishing, and not merely a thin soup, weak cocoa, and uncooked fruit. They should give a child protein-containing food in the form of meat, fish, eggs, purée of peas or beans, or milk, with a starchy vegetable or cereal, a green vegetable, and some cooked fruit. The educational effect of such meals on the child would be most valuable. The present campaign for saving food was excellent and necessary, but more stress might well be laid on the fact that it was possible to buy sufficient nourishing food if the available money were properly spent.

Dr. MORRIS STARK described an experiment that was carried out under the direction of the Post-Graduate Hospital and the Association for Improving the Condition of the Poor to see whether malnutrition could be helped. By weekly examinations they had been able to tell just what profit the lunches supplied had been to the children. There was no question that a great deal could be done for these children by supplying a proper mid-day meal. One important point was that among

Hebrew children it was customary to attend school for religious instruction after the regular school hours. There should be a campaign conducted to influence these religious schools to shorten their hours. Such a campaign should come from the community worker and should not come from outside.

Dr. ROYAL STORRS HAYNES said that when we looked at the experience abroad we realized that we must expect an increase in malnutrition and we were going to need more malnutrition clinics, feeding in schools, and various expedients for lessening malnutrition. There were a great many pediatricists who felt that their particular training tended to keep them at their usual work instead of putting them into the Service. They had here an opening in this war problem and if they could attack it and help in its solution they would be doing a part, if not all, of their duty to their country. As a section they should take action as to what they should do in their particular community, and if they were successful here they might set an example which other communities would find worth while following. He therefore moved the appointment of a committee to make an investigation of this problem and act in advisory capacity; it should make an investigation of the field, cooperate with other agencies along this line, and should keep informed as to what each man could do and let the section know what might be done in the solution of this problem. (This motion was carried.)

Dr. ROWLAND G. FREEMAN expressed the opinion that while the figures presented showed that the situation was grave it was probable that the trouble was rather an ignorance of food value than simple poverty. There was little nonemployment and wages were good, and while the cost of food had increased considerably, sufficient calories might be purchased at little cost; for instance, 2,500 calories of oatmeal cost only 9½ cents, and of hominy only 15 cents. The trouble was that people did not know the nutrient value of different foods or the necessity for a balanced ration of sufficient bulk. Dr. E. K. Dunham had devised perhaps the best method of representing food values in plaster casts made in imitation bread, butter, cheese, vegetables, and fruits, each representing 100 calories. This gave a concrete illustration of comparative food values, and if such casts could be shown in popular lectures, with instruction about food balance and the necessity for food bulk, much underfeeding and defective feeding could be corrected.

Dr. JAMES PORTER FISKE thought there was no objection to acting along the lines indicated and that a nationwide interest in this subject should be aroused without maintaining that there was any real hardship impending. The large number of recruits that were rejected because of physical unfitness and underweight could be used as an argument to show the need of more attention to the subject of proper nutrition and better hygiene, and this could be done without exciting alarm as to an actual scarcity of food.

Dr. JACOB SOBEL said there was no doubt as to the need of an answer to the question what was to be done to solve the problem of malnutrition. In addition to the one means that had been suggested, the school lunches, the Bureau of Child Hygiene of the Department of Health exercised special foresight when it organized cooking classes for mothers at the fifty-nine baby health stations, the object of which was to instruct mothers in the purchase, preservation, care, and preparation of food, and the ways of adapting it to the needs of the growing child. In carrying out this plan attention had been given to the needs of the locality and to the racial needs. This work had been done through the cooperation of Teachers College of Columbia University, Pratt Institute, and the Mayor's Committee. They had tried to teach people to adjust themselves to the present condition, how to prepare food, how to establish a family budget, and to show them how a dollar might be made to purchase the largest amount of food of the greatest value. Dr. Sobel emphasized that malnutrition was not a matter of food *per se*, but of other factors as well, and urged that the time allotted for the midday lunch be extended. He believed that by lengthening the school lunch hour so that children would have time to eat a meal we might hope to see an improvement in the nutrition of the school children.

Dr. CHAPIN, in closing, agreed with Dr. Sobel that while a good midday meal was important it was also im-

portant that the child should have time in which to eat the meal.

Election of Officers.—Dr. Herbert W. Wilcox was elected *Chairman* of the Section, and Dr. Murry H. Bass *Secretary*.

SECTION ON MEDICINE.

Stated Meeting, Held December 18, 1917.

Dr. EDMUND P. SHELBY IN THE CHAIR.

Observations on the Treatment of Diabetes Insipidus with Infundin.—Dr. JESSE C. M. BULLOWA read this paper which was based on a very careful study of many repeated observations in a single patient. He said he hoped the intensive study of the case would atone for the lack of greater clinical opportunity. The patient was a boy, 15 years of age, who came under his observation on September 6, 1917, complaining of the typical symptoms of diabetes insipidus. When the salt intake was restricted the amount of urine voided was reduced and the specific gravity rose occasionally to 1007, but never beyond that point. On September 24, this boy's weight, which six months before was 136 pounds, had fallen to 113 pounds; the specific gravity of his urine was 1004, and he was passing large amounts. He was then given 1 c.c. of pituitrin hypodermically. The administration of posterior lobe extract had been continued up to the present time with occasional intermissions and changes in the dose. By their observations in the course of the treatment they had succeeded in confirming those of others that there was a marked concentration of the urine about two and one-half to three hours after the injection. The specific gravity usually reached 1020. Associated with this rise in specific gravity there was a marked diminution in the amount of water excreted. The fall in the specific gravity was gradual, the effect of the dose as measured by the increase in specific gravity being about seven hours. There was no acute thirst until fourteen or sixteen hours after receiving the drug. They had found the optimum dose of infundin to be 1.2 c.c. They had also used other preparations of pituitary extract. A single dose induced, in about two minutes after the injection of the drug, marked pallor of the skin, dilatation of the pupils and headache, accompanied by a slowing of the heart and a fall in the blood pressure. The pallor of the skin lasted about fifteen minutes and the fall of blood pressure forty-five minutes, when it returned to normal. A fall in the blood pressure was no measure of the benefit to be obtained in relieving the patient's symptoms. They observed the effect of a single dose, as shown by charts, of the same dose divided, of the large dose repeated, and the effect of drugs which have a similar physiological action on smooth muscle and the sympathetic nervous system. They had given the drug by mouth without producing any effect and had also given the whole gland minced orally without benefit. They had observed the excretion of phenolsulphonephthalein given when the patient was not under the influence of the drug and when the drug was exerting its maximum effect. The drug apparently caused a retention of water which was rapidly lost when the patient was allowed to escape from the effect. In short, they had a moderately emaciated patient with a primary polyuria of severe grade in whom hypodermic injections of infundin in optimum doses possesses an antidiuretic action. When this dose was diminished or successively increased a favorable antidiuretic action was not obtained. In view of the fact that tuberculosis as the terminal event in diabetes insipidus had been emphasized, Dr. Bullowa said he wished to show x-ray plates which indicated some infection of the lungs in this case. It had occurred to him that a tuberculous lung infection might be primary and might act through the presence of a pituitary cytotoxin in the production of the nephrosis.

Treatment of the Epileptic Based Upon a Study of the Fundamental Makeup.—Dr. L. PIERCE CLARK read this paper. He said that the gloomy view of the past in the therapy of tuberculosis, with its nauseous drug compounds and easements of narcotics, had been largely superseded by the rational one of fresh air, sunlight, proper nourishment, and an intelligent living regimen.

Such a parallel of progress in therapy was on its way in handling many psychoses and neuroses today, and nowhere was the portent of a change more patent than in the beginning rational therapy for epilepsy. As we had come to recognize and treat tuberculosis in the incipient stage, so we were beginning to realize that so-called idiopathic epileptics were rarely if ever free from the hall marks of their disorder in physical and mental traits during seizure intervals, and in point of fact they had need of the broadest possible therapy to cover their entire life activities. He traced out the analogy between tuberculosis and epilepsy in respect to prognosis, stating that the detection of epilepsy at the presence of a grand mal attack for hopeful treatment was not essentially better than the detection of tuberculosis when it had reached the stage of abscess and cavity formation, but a small percentage of either being restored to health. The analogy might be carried further; the stage of extensive tuberculous consolidation had about the same prognosis as that of an essential epilepsy detected at its mildest beginnings in petit mal or protean manifestations of rank periodic seizures. About 10 per cent. of the latter were fully restored or brought to a more or less permanent arrest. When epilepsy could be detected before any crude manifestations of attacks as such had occurred, then in the early stage of potential epilepsy, as in the early diagnosis of lymphatic involvement in the tuberculous, might it not be hoped that the former would have as favorable prognosis as the latter? We already knew crudely what some of these constitutional factors were as shown in analyses of epileptic individuals. They consisted of a makeup of supersensitivity, egotism, and such a defective primary endowment of instincts that such individuals failed of an easy adjusted or a rich emotional life during their childhood and adolescence. The fault was quantitative as well as qualitative, thus differing from these traits found in normal individuals. When this latter statement was fully recognized the diagnosis of the epileptic makeup would be somewhat easier. Inasmuch as for some years to come our main efforts at correcting or bettering the life and disorders of the epileptic would have to be centered upon him as an individual badly adapted for life in the home, society, or in special sanatoria we should have to increase our efforts to open and make keener his opportunity to objectivate his peculiar type of personality, his hopes and ambitions, into a properly adjusted and selected environment. It was therefore highly important to study individual cases with this end in view. Dr. Clark then cited three cases showing the methods adopted which had been successful in adjusting these individuals to a certain extent at least to their environment. One of these cases was that of a young woman with an undervitalized endowment, born of an elderly alcoholic father and a tuberculous mother. She was inordinately sensitive to sounds of all kinds and very narcissistic and mother-attached. In the failure of a proper adaptive training and being, on the contrary, allowed to mould the environment as she liked rather than she herself making the adaptation, she got on fairly well until the more specific adult demands of living an independent life at the death of the foster parent and a finally unmodifiable marriage situation occurred. She then showed the earlier manifestations of weepings because of hurt feelings, day-dreaming, and when these failed to be of sufficient relief a grand mal epilepsy seemed to have developed. The therapy in this particular case consisted in talks on the defects of her endowment and childhood training and their results. Then followed similar talks with the husband and relatives requiring them to first remove the life stresses so that the patient might regain her normal physical health and proper mental poise. She was advised to discard the numerous patent medicines containing large quantities of bromide which had already given her bromism and a marked stomach and bowel disorder. She was then urged to take music as a study and also to teach it, both being agreeable to her, and each carrying its own pleasure and discipline. In this way she was started on the roadway to better mental and physical health. In closing, Dr. Pierce stated that all three cases which he cited had a fairly poor prognosis. He said he could not too strongly urge that the epileptic as well as the epilepsy be the future object of earnest

treatment, and this by studying as carefully as possible the fundamental makeup of the primary life endowment and basing our therapy largely upon that.

The Endocrine Origin of Muscular Dystrophy.—Drs. N. W. JANNEY and S. P. GOODHART made this presentation which was illustrated by lantern slides and roentgenographs.—Dr. Janney stated that muscular dystrophy was a general disease, as it was accompanied by characteristic changes in bones and other organs. Its endocrine origin had been suspected on account of its symptomatology including dwarfism, peculiar distribution of hair and subcutaneous fat, trophic changes in nails, skin, etc., as well as its appearance in conjunction with endocrine diseases. Moreover the bone lesions resembled those occurring in endocrine conditions. Improvement had occurred on administration of ductless glandular preparations. Nine representative cases of muscular dystrophy were accordingly studied in the metabolism ward of the Montefiore Hospital in order to ascertain whether changes were present which would point to an underlying endocrine disturbance. The results might be summarized as follows: Low creatinine values in blood and urine, the abnormal appearance of creatine in urine, hypoglycemia in all cases. With the help of a new blood sugar tolerance test there was detected in the majority of cases studied a delay in the assimilation of sugar. Hypoglycemia was an indication of hypofunction of various endocrine glands. It was present after epinephrectomy. In a series of dogs it had been found constantly present by Janney and Isaacson after thyroidectomy. In these cases also the blood tolerance test showed decreased assimilability of glucose. Hypoglycemia was also observed in hypophysial dystrophy and Addison's disease. The hypoglycemia and consequent deficient nutrition of bone, muscle and tissues might account in general for the lesions of muscular dystrophy. Creatine was known to increase in muscles in a state of undernutrition, and to appear in the urine when the carbohydrate metabolism was disturbed, or carbohydrates omitted from the diet. The low creatinine values could be accounted for as compensatory for the creatine excretion and as an indication of the decrease in general muscular efficiency. The results of the research seemed sufficient evidence to ascribe an endocrine origin to muscular dystrophy. The study had been reported in more detail before the annual meeting of the American Medical Association of 1916, Section on Neurology, and in an article in course of publication in the *Archives of Internal Medicine*, in which the protocols appeared.

Dr. L. PIERCE CLARK said that he was more or less familiar with the work that was being done along the lines that had been presented this evening; the paper was interesting and showed that the studies were carried out with a great deal of care. He was rather surprised at the mixed clinical types that were under observation, that was, cases in which there were so many factors suggestive of acromegaly and the possibility of central nerve involvement. In a series of his own cases at Randall's Island, some six or seven, who were more or less permanently located there, nearly all kept to the pure type as described in the textbooks for the pseudohypertrophic paralyses. As far as he was able to observe they did not show acromegalic features. He was inclined to believe that the abiotrophic conception of Gowers and Edinger was the best explanation for these disorders. It was well known that this conception had been used particularly in those disorders of the body where there was a general giving out of some particular system, circulatory, respiratory, or muscular, before the individual as such became senile. It was interesting to him to see that there was endocrine disturbances in these disorders either as a pure coincidence or as a result of the dystrophies, and it might be just possible that in time it will be found as the authors contended that the endocrine disturbance was a direct promoter of this particular type of dystrophy. However, one must bear in mind that not a few cases were being reported, especially by the improved anatomic studies, to be associated with degeneration in the nervous structures and that such evidence as presented this evening would, of course, go far toward bringing endocrine causation into direct relationship to the whole degenerative process, but there ought to be studies made to control these findings in conditions of pareses,

in senile degenerations and in conditions of extreme wasting in the tuberculous and in chronic exhausting psychoses. We also knew that some chemical findings similar to those reported had been found in athletes undergoing extreme endurance tests. Until these collateral studies could be made confirmatory or could be excluded from consideration, one would be inclined to think of the endocrinic causation as here presented in the paper as not sufficiently conclusive, interesting though such studies might be in general.

Dr. JANNEY in closing, said that Dr. Clark's question as to whether the endocrine disturbances were concomitant with, or causative of, the changes in the various organs seen in muscular dystrophy was indeed well taken. Light on this problem was afforded by control studies. If the metabolic disturbances found in muscular dystrophy were due to endocrine hypofunction, they should not be present in other conditions such as rheumatoid arthritis, where even as great asthenia and muscle wasting but no endocrine involvement were present. Blood sugar determinations made in several cases of this nature revealed normal blood values which had also been reported in one similar case by McCrudden and Sargent. Evidently the metabolic changes of muscular dystrophy were not merely the concomitant phenomena. As they were the same as those found in other endocrine dystrophies and were shown in animal experiments to follow removal of ductless glands, the weight of evidence was in favor of regarding muscular dystrophy as an endocrine dystrophy of more general nature.

The Physiology of Aerophagia.—Dr. JOHN L. KANTOR read this paper. He stated that if a sufficiently large group of individuals were examined, it would be found that the majority belched after eating, a smaller number would be able to belch on request, and a very few would be able to swallow air when asked to do so. In addition a certain proportion would be found to be unconscious belchers or air swallowers, whereas a final group would be unable to belch or to swallow air even after making every effort to acquire the practice. Air might enter into the stomach in one of two ways; it might be either carried down with the fluids and solids, or it might be gulped down alone. After reviewing the description of the act of deglutition given by various physiologists the writer agreed with Kraus that too little importance was generally attached to the phenomena associated with the cardia and that it would be more in harmony with the latest studies to speak of the swallowing act as composed of three rather than two chief periods, namely, a buccopharyngeal period, and esophageal period and a cardiac or cardiogastric period. He reviewed the act of deglutition from this standpoint, describing his experimental studies of the problem with the aid of the fluoroscope, which were undertaken with the idea of establishing the relation between the swallowing sounds and the entry of air into the stomach. The chief findings were that the bolus was found to reach the cardia in one or two seconds, presumably depending on the amount swallowed and the force employed in the effort. As a rule the food began to penetrate the cardia in a thin stream without any delay whatever. In every case a bubble of air was seen at the top of the food column. No peristaltic waves could be made out at any time, the barium columns seeming to simply sink down into the stomach. In every case in which the second swallowing sound was heard it occurred immediately after the disappearance of the last portion of food through the cardia. The time of occurrence, as well as the number of swallowing sounds, depended entirely upon the position and distribution of the air in the bolus. The essayist then described the mechanism of air gulping and related his experiments with two subjects who were skillful air swallowers. It was found that five or six gulps were sufficient to distend the fornix and tubus of the empty stomach, and in some cases the pyloric vestibule as well. The gulping of air into the filled stomach not only raised the diaphragm but caused a depression of the food level as well with an associated broadening of the stomach through the tubus. When air was swallowed with food in the erect posture there was very little opportunity for the former to go through the pylorus. By far the greater portion was belched up long before the rest of the stomach contents were evacu-

ated. In the reclining position the entrance to the pylorus seemed more accessible. The writer concluded that in general gas accumulations in the upper digestive tract had atmospheric air as their basis. This air was introduced by ordinary swallowing or by the mechanism known as gulping. The difference between the swallowing of air and that of food depended to a large extent on the influence of gravity. As a result the swallowing mechanism showed peculiarities described in this paper. By means of fluoroscopic examinations it could be demonstrated that the so-called swallowing sounds were produced by the entry of air into the stomach. A close study of the mechanism of deglutition showed the advantage of describing the complete act of swallowing as consisting of three instead of two periods, as above mentioned.

Dr. S. J. MELTZER discussed this paper (see page 100).

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE MEDICAL EXAMINATION BOARD.

June 11, 12, 13, and 14, 1917.

ANATOMY.

1. Name the muscle that moves the humerus (a) forward; (b) backward; (c) inward.
2. What bones form the orbital cavity?
3. Describe the crystalline lens and state what tissues are in contact with it.
4. Through what arteries is the collateral circulation carried on after ligation of the subclavian artery?
5. Give point of opening of parotid duct, submaxillary duct, and sublingual ducts.

PHYSIOLOGY.

1. Give the physiology of the production of animal heat.
2. Name the functions of the medulla oblongata.
3. In proportion to weight, what is the average amount of blood in man? How is it renewed after hemorrhage?
4. Give the mechanism of respiration.
5. What are the internal secretions? Give their source and action.
6. Give gross structure and describe the mechanism of urinary excretion.
7. Name the active principles of digestive secretions and state briefly how each affects the food.
8. Describe the effect of an excessive starchy diet.
9. Mention the facts and conditions that favor absorption, and those that retard it.
10. Define reflex action and give examples.

CHEMISTRY.

1. Name three common poisons used for suicidal purposes and the chemical antidote for each.
2. How do you distinguish chemically between urea and uric acid?
3. Give some ordinary chemical tests for recognizing potable water.
4. What is colloidal chemistry? What bearing has it on medicine?
5. Discuss briefly diacetic acid in urine. How determined?

MATERIA MEDICA AND THERAPEUTICS.

1. Give dosage and indications for three remedies used in rheumatism; malaria; jaundice.
2. Name and give dose of two drugs belonging to each of the following classes: (a) diuretic; (b) cathartic; (c) emetic.
3. Name the official preparations of bismuth and state how administered.
4. Apomorphine hydrochloride; give dose and its principal use.
5. Give indication and dosage of aconite; belladonna; digitalis.
6. What is the dose, describe the action, and state the use of mild chloride of mercury and corrosive mercuric chloride.
7. In case of high temperature what are the three

most efficient and safest antipyretics that could be used? Give mode of administering.

8. Explain the physiological action of the salines. Name three and give the dose of each.

9. Name two principal serums and vaccines. Give therapeutic use, dose and mode of administration of each.

10. Define (a) cardiac stimulant; (b) cardiac sedative; (c) cardiac tonic.

DIAGNOSIS.

1. Describe Raynaud's disease.
2. Give clinical signs of empyema of thorax.
3. Differentiate chronic cholecystitis, ulcer of duodenum, and chronic appendicitis.
4. Differentiate rupture of appendix and rupture of gall-bladder.
5. Differentiate pleuritis left side and pericarditis.
6. Differentiate stone in ureter of right kidney and acute appendicitis.
7. Give early signs of cerebral softening.
8. Describe symptoms establishing diagnosis of acute pancreatitis.
9. Describe typical case of ptomaine poisoning.
10. Describe locomotor ataxia.

ANSWERS.

ANATOMY.

1. *A muscle that moves the humerus (a) forward, biceps; (b) backward, latissimus dorsi; (c) inward, teres major.*

2. *Bones which form the orbital cavity: Frontal, malar, superior maxillary, lacrymal, ethmoid, sphenoid, and palate.*

3. *The crystalline lens is a transparent, biconvex, solid body, enclosed within an elastic capsule to which the suspensory ligament is attached. Anteriorly, it is in contact with the iris; posteriorly with the vitreous body.*

4. *Collateral circulation after ligation of the subclavian artery (third part): The suprascapular with the dorsalis scapulæ; the posterior scapular with the subscapular, and the circumflex branches of the axillary; the internal mammary, and superior intercostal, with the long and short thoracics of the axillary and the deep epigastric.*

5. *The parotid duct opens in the mouth opposite the second upper molar tooth; the submaxillary duct opens on the floor of the mouth on a papilla by the side of the frenum of the tongue; the sublingual ducts open separately on the floor of the mouth, one of the larger ones opens into or by the side of the submaxillary duct.*

PHYSIOLOGY.

1. *Heat is developed in the body, by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the brain; (4) the heart, and (5) the thermogenetic centers in the brain, pons, medulla, and spinal cord. (It also is produced by the food and drink ingested.)*

"The immediate source of the body-heat is to be found in the chemical changes which take place in all the tissues and organs of the body. Each contraction of a muscle, each act of secretion, each exhibition of nerve-force, is accompanied by the evolution of heat. The chemical changes are for the most part of the nature of oxidations, the union of oxygen with the elements, carbon and hydrogen, of the food principles either before or after they have become constituents of the tissues. The ultimate source of the body-heat is the latent or potential energy in the food principles, which was absorbed from the sun's energy and stored up during the growth of the vegetable world. In the metabolism of the animal body the food principles are again reduced through oxidation, directly or indirectly, to relatively simple bodies, such as urica, carbon dioxide, and water, with a liberation of a large portion of their contained energy which manifests itself as heat and mechanical motion."—(Brubaker's *Physiology*.)

2. *The functions of the medulla oblongata are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of*

gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contains the cardiac and vasomotor centers.

3. *The total quantity of blood was formerly said to be about one-thirteenth of the weight of the body; recently this figure has been altered to one-twentieth of the body weight.*

Regeneration of blood after a hemorrhage: "If the bleeding does not go on to death the blood is restored by absorption from the tissues or from the food taken in; the first to be absorbed being the serum sanguinis, with the dissolved salts, and then the albumen. A longer time is required to form new red blood-corpuscles. Regenerated blood is at first abnormally watery and poor in cells. As a result of the greater flow of lymph into the blood the number of white blood-corpuscles is greatly increased, and then their number falls off; the red blood-corpuscles again attain their usual number, and the composition of the blood gradually returns to the normal. We do not as yet know certainly how the restoration of the red blood-corpuscles takes place. The most generally accepted view is that colorless corpuscles are being constantly formed in the lymph glands, in the spleen, in the bone marrow, and in the liver, and a certain number of these colorless corpuscles change into the red disks."—(Tillmann's *Surgery*.)

4. *"Respiration is carried on under ordinary circumstances by the diaphragm and external intercostals enlarging the chest and sucking air into the lungs, followed almost immediately by the recoil of the elastic lungs and ribs forcing out the air so inspired. But when there is a more than ordinary venous condition of blood in the system greater efforts must be made to supply the lungs with oxygen, and muscles not ordinarily employed in the effort must be brought into play. The arms and scapulæ are fixed by seizing hold of some object, and by bringing into action the trapezius, levator anguli scapulæ and rhomboidei, so as to make firm attachments for serratus magnus, pectorales, and latissimus in their efforts to raise the ribs. Labored expiration in like manner brings extra muscles into play. In labored respiration the nostrils are expanded by the dilatores naris during inspiration, and resume their original size during expiration. The glottis is widely open during inspiration, while it is narrowed during expiration. These movements of the glottis occur during ordinary breathing, but are exaggerated during difficult breathing."*

*"Breathing is a reflex act, capable of being modified by the will. The nerve-center is situated in the medulla, the afferent nerves are the vagi; the efferent nerves are the phrenics, intercostals, etc. Respiration continues in the absence of consciousness and after the removal of the brain about the medulla; but destruction of a certain small portion of the medulla below the vasomotor center causes the movements at once to cease. This spot is called *nœud vital*. The center is influenced by impulses from without or within—a dash of cold water in the face, a cold bath, an emotion, venous blood in the pulmonary vessels, all call it into action. The center is probably automatic as well as reflex, section of the vagi, thereby interrupting the channel by which the afferent impulses reach it from the lungs, while interfering with the respiratory act does not stop its action. Automatic impulses descend from the center along the efferent nerves. Probably the venous blood circulating through the center itself supplies the stimulus."*—(Ashby's *Physiology*.)

5. *Internal secretions: It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.*

Internal secretions are produced by the liver, pancreas, ovaries, testes, thyroids, parathyroids, spleen, suprarenals, pituitary body, and by the fetus.

The function of the thyroid is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances and (3) it produces an internal secretion.

The function of the thymus is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The function of the suprarenals is not definitely settled; they produce an internal secretion which is probably necessary to life. This secretion causes constriction of arterioles, raises blood pressure, and stimulates muscle fibers which are supplied by the sympathetic system. There is supposed to be some connection between the adrenals and the thyroid and pituitary bodies.

The function of the pituitary body: Complete removal of whole gland or of anterior lobe is followed by death; the anterior lobe is connected with growth, if the gland hypertrophies there follows overgrowth of the skeleton, and partial removal leads to failure of development of the body as a whole and of the sexual glands. The posterior lobe is believed to cause constriction of arterioles, rise of blood pressure, contraction of the involuntary muscles in many viscera, increased flow of urine, and increased secretion of milk.

6. How the urine is secreted is not settled. Bowman's theory was that the water of the urine, together with the soluble inorganic salts, are taken from the capillaries of the glomeruli through the epithelial cells of Bowman's capsule; and that the nitrogenous substances (urea, uric acid, creatinin, etc.) are excreted by the cubical cells which line the convoluted tubules.

Ludwig's theory was that the glomeruli are little more than filters, and that the urine in a dilute form is taken out of the blood by the glomeruli (by filtration), and that in its passage through the tubules these latter absorb some of the water.

Many also believe that urinary excretion is partly due to mechanical filtration and partly to secretory or selective action of the glomerulus; at the same time the epithelium of the tubules is believed to contribute substances to the urine.

Bowman's theory was based on the general structure of the kidneys, the high blood pressure in the renal arteries, and the low blood pressure in the renal veins. According to Ludwig's theory, the function of Bowman's capsule is purely physical (filtration), and the function of the convoluted tubules is physiological (reabsorption).

7.

SECRECTIONS.	ACTIVE PRINCIPLES.	FUNCTIONS.
Salivary	Ptyalin.	Changes starches into dextrin and sugar.
Gastric	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
Pancreatic ...	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal ...	Invertin.	Converts maltose into glucose.

8. The effects of an excessive starchy diet, are: Dyspepsia, flatulence, diarrhea, obesity, and glycosuria.

9. "Factors favoring absorption: (1) The valvulae conniventes greatly increase the area of the intestinal surface, and by their shelf-like formation delay the

advance of the chyme. (2) The villi of the intestine not only increase the area, but are the special organs of the function of absorption. (3) The contraction of the intestine upon its fluid contents also favors, mechanically, the filtration of the contents through its walls. Conditions favoring food absorption: To be absorbed by the blood vessels or lacteals we must have substances in a fluid state, and the more dilute in solution the more ready the absorption; insoluble substances are not appreciably affected by this process, nor are any dense solutions readily taken up. The rapid removal of the absorbed matter and the renewal of fresh blood in the capillaries are of importance. Thus if the portal circulation is obstructed, so that the blood is circulated slowly, or the capillaries are tense from intravascular pressure, absorption will be slow."—(Collins and Rockwell's Physiology.)

10. Reflex actions are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the reflex arc, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

CHEMISTRY.

1. Three common poisons used for suicidal purposes: (1) Carbolic acid, antidote sodium sulphate or alcohol; (2) corrosive sublimate, antidote white of egg or milk; (3) arsenic (paris green), antidote freshly prepared solution of ferric hydroxide.

2. Urea is readily soluble in water; uric acid is almost insoluble. Test for urea: To a few drops of a solution of urea upon a watch glass add a few drops of Millon's reagent, and heat; a yellow color is produced which changes to red. Test for uric acid: Moisten a little uric acid in a porcelain capsule with a few drops of nitric acid; heat on a water-bath until dry; a yellow or red residue remains; then cool it, and add a little ammonium hydroxide solution; the color becomes a red-violet or purple.

3. A potable water should be clear, cool, colorless, odorless, as free as possible from dissolved organic matter, and should not contain more than three or four parts of chlorine in 100,000 parts of water.

Sulphuretted hydrogen may be detected by a black streak which follows when a solution of lead acetate is allowed to flow gently over the surface of the water.

Recent sewage contamination is detected by the rapid decolorization of a solution of potassium permanganate.

Nitrites may be detected by adding a solution of potassium iodide (free from iodate) and starch to the water, and then adding some sulphuric acid; a blue color promptly results in the presence of nitrites.

4. Colloid chemistry is the chemistry of colloid substances, or of substances in a colloid state; practically all biochemistry is colloidal chemistry. The building up of the living tissue from the products of absorption, cell life, all the life processes in the human body, the maintenance of water in the tissues, the phenomena incident to fertilization and the early development of the embryo, the process of growth, the nature of muscular contraction, the problems of secretion, edema, inflammation, and nephritis are some of the more important problems whose solution depends on colloidal chemistry.

5. Diacetic acid is often found in the urine with acetone and beta-oxybutyric acid in the following conditions: Starvation, diabetes mellitus, some of the acute infectious diseases, the pernicious vomiting of pregnancy and eclampsia, disturbances of the digestive tract, and after-poisoning by chloroform. Diacetic acid is detected by slowly adding a solution of ferric chloride to the urine, when a Bordeaux-red color appears; this color disappears on boiling.

MATERIA MEDICA AND THERAPEUTICS.

1. *Three remedies used in rheumatism*: (1) Sodium salicylate, gr. xx every two or three hours until the pain is relieved; (2) sodium bicarbonate, 5j to 5jss every three hours until the urine becomes alkaline, when the dose is reduced; (3) cold bath for the hyperpyrexia.

Three remedies used in malaria: (1) Quinine, 15 grains three times a day until the temperature is normal, when the dose is reduced; (2) strychnine sulphate, gr. 1/40 three times a day as a tonic and for the anemia; (3) methylene blue in 2 grain doses has also been used.

Three remedies used in jaundice: (1) Sodium phosphate, 1 dram every four hours, in the catarrhal form; (2) potassium sulphate, 30 grains well diluted, as a saline purgative; (3) *fel bovis purificatum*, 7 grains, to stimulate the hepatic secretion.

2. *Two diuretics*: (1) Potassium citrate, dose 15 grains; (2) infusion of digitalis, dose 2 drams.

Two cathartics: (1) Castor oil, dose 4 drams; (2) elaterin, dose 1/10 grain.

Two emetics: (1) Apomorphine hydrochloride, dose 1/12 grain by hypodermic method; (2) tartar emetic, dose 1/2 grain.

3. *The official preparations of bismuth* are: Bismuthi betanaphtholas; bismuthi et ammonii citras; bismuthi subcarbonas; bismuthi subgallas; bismuthi subnitras; bismuthi subsalicylas, and magma bismuthi. They are administered by the mouth, and also applied externally as a dusting powder. The insoluble salts are generally given suspended in mucilage.

4. The dose of apomorphine hydrochloride is 1/20 grain as an expectorant, 1/6 grain as an emetic (administered by mouth), and 1/12 grain as an emetic (administered hypodermically). Its principal use is as an emetic.

5. *ACONITE. Indications*: In fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritus, herpes, chilblains, etc. *Dose* of aconite 1/2 grain.

BELLADONNA. Indications: To relieve pain, relax spasm, check sweating, as a mydriatic, to check griping of purgative; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough. *Dose* of belladonna, 1 grain (of the leaves), 3/4 grain (of the root).

DIGITALIS. Indications: Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic, and it is used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. *Dose* of digitalis, 1 grain.

6. *MILD CHLORIDE OF MERCURY. Dose*, 2 1/2 grains (as a laxative), 1/4 grain (as an alterative). *Action*: Externally, mildly irritant and stimulant; absorbed by skin, by lungs. Internally, laxative and purgative; indirect cholagogue.

Uses: Externally, stimulant for syphilitic and non-syphilitic sores, itching, vapor bath in syphilis. Internally, as general laxative or purgative, vomiting from congestion of stomach; congestion of liver, functional or organic; cirrhosis, diarrhea, diuretic in small doses; rarely for syphilis.

CORROSIVE MERCURIC CHLORIDE. Dose, 1.20 grain. *Action*: Externally, antiseptic disinfectant, antiparasitic; absorbed by skin, by lungs. Internally, gastrointestinal irritant; produces anemia in large doses; direct cholagogue. *Uses*: Externally, as general antiseptic and parasiticide, yellow wash for itching and syphilitic sores. Internally, alone or with potassium iodide for syphilis, second or third stage; to absorb non-syphilitic, chronic, inflammatory formations, e.g. interstitial nephritis.

7. *The three best and safest antipyretics* are: (1)

Cold water, administered externally as a bath, cold pack; (2) *quinine*, administered internally, generally in a single dose (about 30 grains) in capsules or suspended in milk; (3) *aconite*, administered internally, in doses of 4 or 5 minims of the tincture.

8. *Salines* "act by stimulating the intestinal glands to increased secretion, and by their low diffusibility impede reabsorption, causing an accumulation of fluid in the intestinal tract which, partly from the effect of gravity and partly by gentle stimulation of peristalsis excited by distention, reaches the rectum and produces a copious evacuation."—(Potter.)

Three salines: Magnesium sulphate, dose 4 drams; potassium bitartrate, dose 30 grains; sodium phosphate, dose 1 dram.

9. *TWO SERUMS*: (1) *Antidiphtheritic serum* (against diphtheria); administered subcutaneously; dosage, average about 3,000 units, immunizing dose for a well person about 500 units. (2) *Antitetanic serum* (against tetanus); administered subcutaneously or into the spinal subarachnoid space; dose, 10 to 20 c.c.; repeated if necessary.

TWO VACCINES: (1) *Typhoid vaccine* (against typhoid fever), administered subcutaneously into the arm, giving 500 million bacteria at the first injection, and two further injections of one billion bacteria at intervals of ten days. (2) *Vaccine virus* (against smallpox), used by inoculation.

10. *Cardiac stimulant* is an agent which rapidly increases the force and frequency of the pulse in depressed conditions of the heart.

Cardiac sedative is an agent which lessens the force and frequency of the heart's action.

Cardiac tonic is an agent which stimulates the heart muscle and makes its contractions slower and stronger.

DIAGNOSIS.

1. *Raynaud's disease* is a very rare disease, characterized essentially by symmetrical gangrene. The cause is unknown, but there are three chief theories brought forward to explain the disease. These are that it is due to (1) endarteritis obliterans, (2) to peripheral neuritis, (3) to vascular spasm. The affection is associated with some disturbance of the vasomotor system, as a result of which local stagnation of the peripheral circulation occurs. In consequence of this there arise localized anemia, congestion, and finally gangrene, symmetrically distributed. The condition is observed most often in neurotic women under thirty years of age and in children. Pain is a prominent symptom.—(Hughes' *Practice of Medicine*.)

2. *Empyema of the thorax*. The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocartilaginous tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways. (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary.

Symptoms: Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

3. In *chronic appendicitis*, there is a history of one or more previous attacks in which no operation was performed, or perhaps the diagnosis was not made; attacks of pain occasionally occur in the right iliac fossa; there are various digestive disturbances, such as constipation, diarrhea, flatulency; a tender mass may be detected on palpation over the painful area; the pain generally incapacitates the patient for a day or two. In *chronic*

cholecystitis, the history points to the liver or gall-bladder; the pain and tenderness are just beneath the costal arch; the pain is more severe and may radiate to the right shoulder; the pain is not relieved by eating, and it does not come on after every meal. In *duodenal ulcer*, there is a history of pain in the epigastrium about two to six hours after eating, and this pain is relieved by eating; it generally occurs in middle-aged people, and the pain may be referred to the shoulder or right iliac region; blood is passed with the feces.

4. In *rupture of the gall bladder*, the immediate symptoms are those of shock and severe pain in the right hypochondriac region; acute peritonitis follows: jaundice will be present; bile will be found in the urine, and the feces will be clay colored. In *rupture of the appendix*, the pain is at first in the right iliac fossa, but may spread over the lower abdomen or even the entire abdomen; vomiting and constipation are present; the abdomen is tender and distended; there are marked constitutional symptoms, but collapse is not very noticeable.

5. *Pleuritic and pericardial effusion*: "In pericardial effusion dyspnea is a more prominent symptom than in pleural effusion. In the former the heart is not displaced to the right, as in pleural effusion. In pericardial effusion percussion shows the area of flatness to be circumscribed, and to be most marked in the axillary region. Along the posterior margin of the left pleura normal pulmonary resonance is obtained, whereas in pleural effusion a flat note is elicited over this region. In pericardial effusion the heart-sounds are distant, feeble, or muffled, while in pleural effusion the quality of the heart-sounds is unaltered." (Anders and Boston's *Medical Diagnosis*.)

6. In *appendicitis*, the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *right ureteral calculus*, the pain may be excruciating, and radiates down the course of the ureter and to the genitals; x-ray may show the calculus, and the passage of a ureteral catheter may also demonstrate it; cold sweat, vomiting, strangury, and collapse may be present, and the other signs of appendicitis are absent.

7. *Cerebral thrombosis* is characterized by a gradual onset. It is most common in the aged and is manifested by persistent headache and vertigo of varying intensity; alterations in the character, the patient becoming irritable, morose, and despondent with periods of absent-mindedness; disorders of vision, impairment of memory; hesitating and mumbling speech; impaired locomotion with muscular weakness and trembling; and finally paralysis. Hemiplegia is common and may appear gradually or be preceded by sudden insensibility; the condition progresses and ends in dementia and finally death from exhaustion. Rarely, a collateral circulation is established and partial or complete recovery occurs.

In *cerebral embolism*, the symptoms occur suddenly and may be mild or grave in character. In the *mild variety*, there are sudden and severe vertigo, confusion of mind, muscular twitchings, usually one-sided, and vomiting, followed by hemiplegia, most frequently of the right side, the intellect remaining clear but hesitating. After some weeks or months the paralysis usually disappears and recovery is complete. The *grave or apoplectic variety* is manifested by sudden headache, vertigo, flushing or pallor of the face, sudden unconsciousness, often preceded by a sharp cry, and complete muscular relaxation followed by death, or a gradual return to consciousness with hemiplegia, usually right-sided, and aphasia. The loss of speech may last several weeks or months or may be persistent. The mind may remain normal or may be greatly enfeebled, the reason and judgment be clouded, and after a varying period dementia develops, being followed by exhaustion and death.—(Hughes' *Practice of Medicine*.)

8. *Acute pancreatitis*.—"The occurrence of sudden severe pain in the epigastrium, accompanied by faintness or collapse and by vomiting, should lead one to suspect an acute pancreatitis, if the other acute conditions which occur in the upper abdominal region can

be excluded. In addition to the above triad of symptoms, there is muscular rigidity and tenderness over the epigastrium, and a tender mass can be felt here. If suppuration occurs a rise of temperature persists after the subsidence of the acute symptoms, and with it a leucocytosis. In many cases death occurs on the second to the fourth day of the disease. In the acute cases there is marked constipation, but this is not so absolute but that flatus can be passed by the aid of an enema. This serves to differentiate it from an intestinal obstruction. There is also fat in large quantities in the stools. The pain may be so severe as to produce syncope or collapse, and it has a tendency to become paroxysmal. The pain is soon followed by distention in the upper abdominal region, which later becomes general. There is usually slight jaundice present, but this may be quite intense, if the ampulla of Vater is completely blocked by a calculus. The preceding description applies to either the acute hemorrhagic, gangrenous, or suppurative varieties."—(Eisendrath's *Surgical Diagnosis*.)

9. *The symptoms of ptomaine poisoning* are: Onset more or less sudden, abdominal pain, persistent nausea and vomiting, chill, diarrhea, headache, weakness, vertigo, faintness, neuromuscular pains, sometimes fever.

10. *Locomotor ataxia* is a disease of the spinal cord, characterized by loss of coordination, characteristic and unsteady gait, a tendency to stagger when standing up with the feet together and the eyes closed, sharp and paroxysmal pains called *crises*, girdle sensation, Argyll-Robertson pupils, and loss of knee-jerk and other reflexes. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia may also be affected and the membranes over the affected parts are adherent and opaque.

In the *pre-ataxic stage*, there may be found: Lightning pains, girdle pains, paresthesia, loss of knee-jerk, Argyll-Robertson pupil, ptosis, and optic atrophy. In the *ataxic stage* there will be found: Incoordination, the ataxic gait, flaccidity of the muscles, loss of muscle sense, various visceral crises, perforating ulcer of foot, brittleness of bones, and Charcot's disease.

(To be continued.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and on acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

PROGRESSIVE MEDICINE. A Quarterly Digest. December 1, 1917, issue. Edited by HOBART AMORY HARE, M.D., Assisted by LEIGHTON F. APPLEMAN, M.D. 466 pages. Illustrated. Price, \$6.00 per annum. Published by Lea & Febiger, Philadelphia and New York.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY, Fiftieth Annual Meeting. Vol. XIV, Part II. 358 pages. Illustrated. Published by The Society, Mercury Publishing Company, Printers, New Bedford, Mass.

THE CONDUCTION OF THE NERVOUS IMPULSE. By KEITH LUCAS, Sc.D., F.R.S. 102 pages. Illustrated. Price, \$1.50. Published by Longmans, Green & Co., London and New York.

THE PRACTICAL MEDICINE SERIES. Vol. VII, OBSTETRICS. By JOSEPH B. DE LEE, M.D. 224 pages. Illustrated. Price, \$1.35. Published by The Year Book Publishers, Chicago.

THE PRACTICAL MEDICINE SERIES. Vol. VIII, PHARMACOLOGY AND THERAPEUTICS, PREVENTIVE MEDICINE. By BERNARD FANTUS, M.S., M.D., and WILLIAM A. EVANS, M.S., LL.D., P.H.S. 384 pages. Illustrated. Price, \$1.50. Published by The Year Book Publishers, Chicago.

Miscellany.

War and Alcohol.—Major W. McAdam Eccles, surgeon to St. Bartholomew's Hospital and First London General Hospital, delivering the Seventh Norman Kerr Memorial Lecture of the Society for the Study of Inebriety on October 9, 1917, took as his subject, "War and Alcohol." He dealt specially with the relationship of the war to the manufacture and use of alcohol. War, he said, alters many preconceived ideas and lays bare foundation truths. Alcohol has a most important bearing on the war. Men like to drink it, the sum of £200,000,000 (\$1,000,000,000) was spent on excisable alcoholic beverages in the United Kingdom and Ireland in 1916 and the output of munitions and ships has been menaced by it. Nearly one-half of the population of the British Isles are total abstainers, the other half drink alcohol, either moderately or immoderately. Alcoholic beverages are drunk for the alcohol they contain far more than for the small amount of food present in them, and the question, therefore, is whether the alcohol is beneficial or harmful to health and efficiency when taken in moderate amounts.

Ethyl alcohol is not an essential food. If taken as a food it is a most expensive and consequently a "luxury" food and a great deal of it is being wasted by human consumption. Alcohol is an essential for manufactures connected with the war, particularly in the production of munitions, and if used for other purposes it is wasted so far as victory is concerned. Continuing, Major Eccles pointed out that alcohol is useful for many industrial, chemical, and scientific purposes. If there is not enough and cheap alcohol for these uses on account of human consumption, there is direct waste. Alcohol is really a drug rather than a food. All the nutrition which can be obtained from alcohol can be obtained from other very much less expensive, and, when taken in normal quantities, harmless foodstuffs.

It is significant that some of the present industrial unrest has resulted from the scarcity and high price of beer, brought about by the necessary action of the Central Control Board. The majority of the female munition workers were able to perform their duties and keep in good health without having recourse to alcoholic beverages. Major Eccles concluded his address by saying: "The saving of money, the better health of the people, their greater efficiency, and, as many believe, the hastening of victory by the disuse of alcohol for human consumption is a matter which concerns every member of the community, and it is the duty of all who know the facts to diffuse them temperately, earnestly, and widely among all classes of the nation. Truly it would be a splendid achievement to win a more decisive and quicker victory over our enemies by the patriotic and self-denying abstinence from alcoholic beverages so wisely inaugurated by the King and his households."—*The Medical Officer*, November 10, 1917.

War Prosperity and Health Conditions in Birkenhead, England.—Dr. R. Sydney Marsden has this year submitted his twenty-fifth annual report as medical officer of health for the county borough of Birkenhead. On this occasion he is

able to show the lowest death rate and infant mortality rates hitherto recorded. Referring to the healthy condition of the townspeople in spite of the difficulties caused by the war, he says that there is no doubt in his mind that this general condition of good health is due largely to the fact that the children are being better fed than in normal years, owing to the men being at war; the separation allowances are going to the mothers, and the women, in most cases, spend them on food and clothing for the children, with the result that the latter have greater resisting power against disease, and infectious fevers have not spread, the number of cases treated in the fever hospital during the past two years showing a marked decline. If this condition of feeding could be continued and better housing facilities could be provided, Dr. Marsden thinks that the death rates might be still further reduced.—*Medical Officer*, November 10, 1917.

Garbage Disposal in New York.—Dr. Joseph A. Shears, in the *Monthly Bulletin* of the New York City Department of Health for October, describes the new method for the disposal of the garbage of the city that is being employed in the plant at Lake Island, Greenridge, Staten Island. This process is the result of twenty-one years of experience and experimentation in the disposal of garbage by the reduction method and is known as the Cobwell System. In this plant there are at present 200 garbage reducers in operation, each having a capacity of five tons. It takes somewhat less than twelve hours to dispose of this amount of garbage.

The most striking advantages of the Cobwell method of garbage disposal over other methods from the sanitary viewpoint are that the garbage is not handled manually and at no time, from its receipt until its final discharge as a finished product, is it brought into contact with the atmosphere; it is thoroughly sterilized and the by-products are practically odorless; there are no gases of decomposition or of combustion, nor is there any condensing, washing, or trapping of odoriferous gases; the effluent water is sterile and free from deleterious matter, and every portion of the material receives the full sterilizing and deodorizing action of the process. A comparison of the efficiency of the Cobwell system with the Arnold system shows that the quantity of grease recovered under the Cobwell process exceeds that recovered by the Arnold process by 10 per cent. The quantity of fertilizer recovered under the Cobwell process exceeds that recovered by the Arnold process by 60 per cent. The aggregate value of all products recovered under the Cobwell process exceeds the aggregate value of all products recovered under the Arnold process by approximately 20 per cent. The comparative value of the fat yield, based on assumed 275,000 tons of garbage as the annual delivery of a quality equivalent to that of the garbage delivered in 1914 and 1915, shows that with the Cobwell process fats sufficient to manufacture 3,500,000 pounds of high explosives and 70,000,000 cakes of laundry soap of standard size can be produced as compared with 2,800,000 pounds of high explosives and 60,000,000 cakes of soap by the Arnold process.

ASSOCIATE VISITING PHYSICIAN TO GOUVERNEUR HOSPITAL.
ASSISTANT VISITING PHYSICIAN TO THE NEW
YORK CITY HOSPITAL.

THE rapidly accumulating laboratory and clinical evidence of the importance of focal streptococcus infections in a very wide range of diseases, from a mild lumbago to an arthritis with permanent crippling, from fruste Graves' disease to a profound neurasthenia, from a slight cardiac derangement to a lethal subacute bacterial endocarditis, or from a mild renal insufficiency to a terminal Bright's disease, impels us to present the following preliminary report with the hope that although inconclusive it may add another suggestive link to the chain and stimulate interest in further attempts to fix the responsibility of this elusive microorganism before its effects have accomplished incurable invalidism.

Billings' and Rosenow's work has been so widely read as to require only the high tribute it properly deserves. Nearly thirty years ago Willoughby D. Miller¹ called attention to infections in the oral cavity and their importance to the general health. A little more than ten years later William Hunter² reported the results of his investigations of oral sepsis and especially emphasized the "sallow complexion and languid condition of such chronically infected individuals." He believed the absorption of toxic products was usually from swallowed pus, and called attention to the direct invasion of the mucosa of structures between the teeth and stomach—tonsils, pharynx, esophagus, and especially the stomach. He also mentions, however, the possibility of direct absorption from the tooth sockets, "the most serious form of sepsis, that of diseased bone," and the possibility of such acute conditions as resulting empyema, meningitis, and osteomyelitis.

In 1909 Hunter published his "Severest Anemias," attributing their cause to a chronic infection.

Ten years ago, impressed by the almost specific action of vaccines in some streptococcus infections,³ one of us, with other observers, began a number of unsuccessful efforts to incriminate this germ and its particular variety by correlating the clinical features of selected cases with some blood test or subcutaneous reaction. Numerous similar attempts have been made by others, but thus far, with the exception of the work on scarlet fever, no very encouraging or useful results have been obtained. Besredka,⁴ working with the serum of immunized horses, found that complement fixation was produced only with the strain of streptococcus producing the immunity. In the same year Besredka and Dopter⁵ applied the fixation test in scarlet fever, but without positive results. During the years since then a number of other workers⁶ have attempted to identify the streptococcus as the cause of scarlet fever, using the complement fixation reaction with antigens made in various ways in order to determine the presence or absence of streptococcus antibodies in the blood of these patients, but with varying results. In 1907 Castex,¹⁰ in four cases of erysipelas, five of scarlet fever, one of puerperal fever, one of pleurisy and arthritis, and one with a streptococcus abscess found the complement fixation test positive in all but three of the five cases of scarlet fever. Swift and Thro¹¹ used the same test and conglutination reaction, and Hastings¹² used complement fixation with antigens made from various bacteria in chronic arthritis.

The accompanying table summarizes our experience with a complement fixation test in a series of cases selected from one of the hospital services and from the private practice of one of us. We have been able to follow up nearly all of the latter group.

In Table II we have rearranged most cases of the same series and so summarized the results of the fixation tests in arthritis and heart disease. Although in a tabular form only suggestive, the clinical course of those private patients which we have been able to follow for a considerable period of time has convinced us of the preponderating importance in etiology and treatment of these minor focal streptococcus infections in many serious conditions of chronic invalidism and stimulated us to further study of more exact and specific methods of diagnosis. The technique used in making these tests was identical with that of the classical Wassermann test, excepting that an antigen prepared from several varieties of streptococci was used. The strains of streptococci from which the antigen was prepared were obtained from clinical cases showing widely varying conditions of streptococcic infection.

ORAL INFECTION.

++++, +++, ++ indicate positive streptococcus complement fixation tests, the degree shown by the number of crosses.

"Pos." indicates merely a positive test of varying degree.

+, =, indicate doubtful tests.

— indicates a negative test.

X indicates a positive, φ a doubtful, 0 a negative Wassermann test.

XX indicates a positive, φφ a doubtful, 00 a negative gonococcus complement fixation test.

The ice-box method of binding complement was used throughout, as it was found that a much greater dilution of antigen could be used by this method than with water-bath at 37° C.

The antigen was prepared as follows: eighteen to twenty-four hour old cultures grown on plain veal agar were washed off with distilled water and extracted in the water-bath at 56° C. for several hours. The suspension was then centrifuged and the supernatant fluid passed through a Berkefeld filter. The filtrate was rendered isotonic by the addition of 0.85 per cent. of sodium chloride, and was standardized against the serum of an immunized rabbit for use as an antigen.

The sera of immunized rabbits were also used as positive controls in making the clinical tests. The hemolytic system and antigen were carefully standardized each day before tests were made and the sera to be tested were always inactivated at 56° C. for thirty minutes.

Streptococcal antigens prepared by the above method did not cross fix with immune sera prepared from other pus producing organisms but immune sera prepared from individual varieties of streptococci gave more or less complete fixation with antigens prepared from any of the other varieties, as well as with antigens prepared from the streptococcus mucosus capsulatus and the pneumococcus.

It was found necessary to test rabbits selected for immunization with great care as the serum of a

large percentage of apparently normal rabbits gives strong fixation with most bacterial antigens.*

Twenty-one of our cases, all but one from private practice, have been followed up very carefully for two years or more, and have very largely recovered or very decidedly improved, due, we believe, to the elimination of a definite focus of chronic infection, usually in the teeth or tonsils. We have tabulated

*A considerable portion of the actual test work was performed by Miss M. P. Olmstead, for whose assistance we wish to express here our obligation and appreciation.

these cases (Table III) with the results of their complement fixation, the focus treated, and the clinical result.

The details of a few illustrative cases, most of them from our series, Table III, follow:

CASE I (Not in series).—An example of a subacute periodic bacteremia in which a reliable test to identify the causative organism would have been of great value early in her disease. Female, 35 years, married. Previously well except for nearly all the diseases of childhood. In November, 1914, she had complained of "lameness" in the first left lower bicuspid, which by x-ray showed an area of decalcification at the tip. Her dentist considered it trivial, but in February, 1915, an abscess developed. The tooth was then drilled into, pus evacuated, the tooth filled, but the abscess promptly filled up and the tooth was again opened and this time treated until all radiographic evidence of any trouble at the root had disappeared, when it was again filled and gave her no trouble until the latter part of the summer of 1915. Then the "lameness" returned, and several weeks later (November) pains began in her joints and muscles. She recovered from one such attack only to have another in a few days and a much more persistent and painful one. Salicylates and strict diet were ineffectual, but the ultra violet ray apparently did help her until December 5, when she was acutely stricken with severe epigastric pain, vomiting and fever. Two days later, when first examined by one of us, she still had the abdominal pain, there was a distinct mitral lesion of the heart with enlargement and a to and fro murmur over the base of the precordia, some congestion at the base of the left lung, a herpes labialis, an enlarged spleen, and a very rigid, tender abdomen. A few weeks later a crop of petechial and purpuric spots appeared and there were frequently recurring areas of inflammation in each lung. Cerebral symptoms soon occurred with frontal headache, blurred vision, and a number of convulsions followed by a left facial paralysis. In February, 1916, a more intense headache returned, accompanied by a complete left-sided paralysis, a slight but persistent hematuria, an enlargement and tenderness of the left kidney and a pleurisy. During the first week in March her joints were definitely and visibly affected for the first time; the hematuria continued, was much accentuated during the administration of hexamethylenamine, but lessened again on its withdrawal. During the last week of the month the frontal headache returned, further visual disturbance, a marked deafness and, coincidentally, the urine showed a large amount of sugar. In April the continued hematuria, a higher and more remittent fever, and a convulsion on the 23d, contributed to a general decline in her condition. Clinical and x-ray examinations of the sinuses, teeth, chest, abdomen, and the pelvic organs failed to disclose any other foci of infection.

Early in May her condition changed rapidly for the worse; cerebral symptoms increased, the circulation was weaker, and the hematuria increased. She was transfused June 1 and 7, the second transfusion apparently benefiting her for a few days. The bleeding, however, persisted and increased, and in spite of three more transfusions she died July 10. There was no essential change in the heart lesion during her illness. Five blood cultures made December 8, January 10, February 19, June 1, and June 21 were all sterile; one culture of the urine, July 4, showed a colon bacillus and a streptococcus; another, January 5, was sterile; a few c.c. of serum from the chest, January 8, was negative cytologically and bacteriologically; the spinal fluid, January 9, was likewise negative. Wassermann examinations of both spinal fluid and blood were negative; two of the extracted teeth furnished cultures of streptococcus viridans and one was sterile. The leucocytes were usually about 12,000; the highest count, in December, was 18,200; the lowest, May 22, being 9600; the hemoglobin (Sahli) at first was 85 per cent., May 22 was 50 per cent., and at the end of her illness it was 65 per cent.

CASE II (No. 42 in series).—An example of a typical subacute infectious arthritis (cause oral sepsis) in which the clinical diagnosis was practically certain, the fixation doubtful, and the treatment, although incomplete, strikingly successful. Female, 42 years, married for 22 years. Her first child was born when she was 23, the puerperium being normal, and at 25 the second child was born, a very difficult labor and a puerperium protracted by a "cold on left lung," which continued for three months. The third child, at 40 years, was born dead and macerated at term. There was no history of other illnesses until seven years ago, when she had the first joint trouble; and for five years she had acute or subacute inflammation of joints; they would become red, swollen and very painful; would so continue for some time, and the acute attack would then subside, leaving a permanently crippled joint. Accompanying the acute part of the trouble, she had fever and sweats. All sorts of treatment were tried, but nothing gave her any relief. Five years ago her teeth began "to drop out," and she has been losing them ever since, but those remaining "give her no trouble." For the past two years (history taken in 1914) she has been in very much better health, has had no acute joint trouble, and has even been able to get around fairly successfully. Three months ago (1914) she came to this country (from Scotland), and one month later the pain and swelling of the joints returned, first in the neck, then in the left elbow and finally in all joints, and accompanied as before by fever and sweats. She was moderately crippled, but although able to come to the office, practically all the joints had been at one time affected; her thyroid was enlarged; she had marked pyorrhea of her remaining teeth and several carious roots; her tonsils were but slightly enlarged; her heart was very rapid, but otherwise appeared normal, and her spleen could not be felt. Urine was 1036, with a trace of albumin, and a culture of the pus about the teeth gave a pure growth of streptococcus viridans, and her blood a doubtful fixation. She was advised to have all the teeth removed, and was given rather intermittently an autogenous vaccine. She would not permit the extraction of all the teeth, but did get rid of the worst roots, and subsequently there was an almost immediate cessation of the acute symptoms, and she was soon able to do her own housework. *Recent report:* A year ago the added drain of a pregnancy and an acute appendicitis was followed by a return of the arthritis, and when last seen (about 9 months ago) there was some subacute inflammation of the finger and hand joints and considerable pyorrhea at the site of the remaining teeth, which she has persisted in retaining.

CASE III (No. 20).—An example to illustrate a "frustrated Graves' disease" in which the streptococcus fixation test was strongly positive and the tonsils were the evident source of infection. Female, 38 years, married, admitted to the City Hospital with a history of scarlet fever at six years, of measles three times. She had one child, a forceps delivery, but otherwise a normal pregnancy, and puerperium. One year ago she had

tonsillitis with "rheumatism" involving both her ankles and knees; she was sick but ten days and has had no recurrence. For the past three months she has complained of dyspnea, nervousness, palpitation, and a slight cough. She was a strong, healthy looking woman with no apparent loss of weight; there was slight cyanosis and evident nervousness. The tonsils were enlarged; there was a chronic pharyngitis, a few enlarged post cervical glands. The thyroid was not notably enlarged; the lungs were clear; heart not enlarged, though at the apex was a sound suggesting a presystolic rumble. Dermographism was marked, and the patellar reflexes exaggerated. Culture of her throat showed a streptococcus, and her streptococcus complement fixation was four plus. At first the temperature ranged from 98 to 100 and the pulse averaged 100. After several days' rest in bed and the administration of bromides the temperature became normal and the pulse averaged 75. Three years later, September, 1916, she was seen again. She was then considerably better, but not well, the most noticeable improvement being during the summer months. Her tonsils had not been treated; she had then a slight enlargement of the thyroid, a tremor, and occasional attacks of tachycardia.

CASE IV (No. 69).—*An example of a double infection both located in the tonsils where a decisive fixation test of proved value would have been of great value to determine the proper treatment at once.* Female, 14 years; had the lesser diseases of childhood, but never had any serious illness. In November, 1912, she contracted a sore throat and cough. A few days later she awoke with a puffiness of her face, and during December her feet and legs were swollen. A diagnosis of acute nephritis was made; she was dieted and given hot packs for several days, improving considerably. Ever since, however, she has had a little swelling of her legs, and lately, at night especially, is so dyspneic she must sit up in bed. On the 18th of April she was admitted to the City Hospital. Her lips were slightly cyanotic; in the heart there was a suggestion of a presystolic murmur at the apex; the liver was barely palpable, and there was a slight but definite edema of the legs. During her stay in the hospital her rectal temperature ran from 98 to 99.5°; her pulse varied from 80 to 100, and her blood pressure was 110. Vision was defective in each eye (no mention being made of the eye-grounds). In the pharynx and throat there was excessive lymphoid tissue; the tonsils were enlarged and cryptic, but there was no sign of acute inflammation in them. The specific gravity of the urine varied from 1020 to 1030, with albumin present in variable amounts from a faint trace to a heavy cloud, and there were always hyaline and granular casts present. Her streptococcus complement fixation was four plus. Cultures from the throat disclosed the presence of Klebs-Loeffler bacillus 10 times in 12 examinations, there being no mention of other organisms present or what the culture showed on the two examinations negative to the diphtheria germ.

CASE V (Not included in series).—*An example to illustrate the value of a reliable fixation test so as to incriminate and more promptly treat the causative organism where two evidently possible sources existed, oral sepsis (streptococcus) and vaginitis (gonococcus).* Female, 30 years, presented a serious, active, and prolonged clinical picture thyrotoxicosis. The history of leucorrhea following a Neisser infection in 1911, but with negative smears from the vagina upon several occasions, and a doubtful gonococcus complement fixation test; as well as the lack of symptomatic benefit following skilled gynecological treatment while under our observation added to its complexity. For some years a rather marked pyorrhea had existed. In 1911 a prolonged low fever puzzled her physician on the Pacific Coast; but its abatement soon after the discovery and treatment of a caries of the jaw from an infected tooth and of an accompanying infection of the adjoining antrum strongly suggested these two foci as the etiological factors. When referred to us for a recurrence of the fever, she also presented a mild arthritis of the spine and distinct though moderate symptoms of Basedow's disease (tachycardia, tremor, nervousness, vasomotor disturbances and a unilateral thyroid enlargement). We felt justified in adding an autogenous

vaccine from an organism (*S. viridans*) isolated from pyorrheal pockets, to the painstaking dental surgery and local gynecological measures. Radiograms, at that time, seemed to confirm the dentist's opinion that the oral sepsis was limited to the existing pyorrhea. Marked improvement in all symptoms followed these measures and persisted for a few weeks after their cessation. A further course of vaccines produced a similar temporary improvement after a recurrence of her symptoms. Finally, despite another negative radiogram and the dentist's conviction that the teeth could not be the source of this recurrence, the latter was finally persuaded to extract a tooth adjoining the old location of the caries and supporting a bridge. A tiny drop of pus was found at its root, furnishing a pure culture of *S. viridans*. With the addition of a new vaccine, her symptoms soon vanished and at last report a couple of years ago, they had not recurred.

CASE VI (No. 68).—*An example to illustrate the chronicity of some oral infections, the complexity of symptoms resulting therefrom, the importance of heeding all possible etiological factors and the value of a decisive laboratory test to guide treatment.* Female, 36 years, suffering from (1) profound neurasthenia for many years; (2) two attacks of slight hematuria without demonstrable cause; (3) subject to frequent severe colds and to infection of adenoids and tonsils; (4)

Diagram of condition before and after treatment in a case showing the vicious circle in oral sepsis.

chloranemic for years; (5) periodic development of facial edema, mostly periorbital; (6) pyorrhea for many years; (7) falling hair and brittleness of nails; (8) leucorrhea; (9) myalgias. (See the illustration.) In addition to pyorrhea a tooth abscess with a sinus which alternately closed and opened, discharging pus, had existed and had been treated from 1901 to 1912, until the patient and her dentist could be persuaded to sacrifice the tooth. Cultures from this pus showed a hemolytic streptococcus and the patient's blood serum a positive complement fixation. A strong psychical disturbance operative from 1903 to 1907 was an important factor in the patient's general condition. Her treatment for several years was symptomatic, general, psychic, local, and prophylactic both to teeth and to mucous membranes of tonsils and adenoids; but no pronounced permanent effect was produced until the tooth was finally extracted in 1913. There was found to be a much wider and more serious involvement than had been supposed, with caries of the bone and a spreading of the infection to the roots of the two adjoining teeth. The relative size of the sectors (1-5) in the circle represents diagrammatically the approximate degree of improvement existing to-day. The mild pyorrhea still existing requires frequent prophylactic treatment, but the patient's general condition is markedly improved.

CASE VII (No. 24).—*Another example of a complex clinical picture where an existing dental sepsis was complicated by a chronic infection of the tonsil, where a decisive fixation test, supported by a more prompt recognition of the apparently primary factor, might have suggested earlier and more beneficial treatment.* Female, 40 years, symptoms of acid dyspepsia (possible ulcer) in 1905, prolonged shock in 1908 followed by pronounced depression and neurasthenia to 1913, cervical arthritis confirmed by radiogram in 1910-1911, lumbago 1911, sciatica 1911, fruste Basedow's disease 1911 to 1912, myocardial insufficiency 1911 to 1913 with palpitation, dyspnea, chills and sweats at night, indigestion,

epigastric fulness and pain and with signs of a dilated heart, mitral insufficiency and an engorged liver. Her dentist, supported by negative radiograms, considered her teeth sound. The treatment followed from 1910 to 1912 and directed against the general symptoms, arthritis, cardiac condition and neurasthenia as well as in 1913 vigorous local treatment to tonsils produced, however, very unsatisfactory results: the patient evidently slowly lost ground. Finally another dentist aided by another radiographic examination reported as follows: "Extensive pyorrhea, apical disease which must have existed for years, four non-vital teeth, and a gangrenous tooth pulp." His prompt efficient treatment, including the extraction of two teeth in 1914, produced an immediate and very remarkable improvement in all the above symptoms. Since then I have only seen the patient once, but her improvement has persisted except for occasional stiffness of neck; a little fatigue and slight dyspnea upon exertion, and some remnant of her general nervous symptoms. She recently reported by letter as being in excellent condition.

An interesting and rather amusing addition to the foregoing, is the following: Tonsillectomy was advised in 1913; but the patient's fear of an operation was so great that it seemed only fair to give her the benefit of further counsel. She was, therefore, sent first to one, and then to another of two of our most brilliant and renowned diagnosticians. From both I obtained the identical diagnosis "neurasthenia," and the same advice for treatment, "remarriage"; but she still has her tonsils, she remains a widow, and since the institution of proper dental surgery, she has not required further medical assistance.

CASE VIII (No. 1).—*An example to illustrate that to a so-called "gouty" individual, a minor infection is of great moment, that a reliable laboratory test would have immediately cleared up the natural doubt as to the infectious or metabolic cause responsible for the symptoms, that prompt eradication of the former was followed by permanent cure and that too despite the patient's age and the severity of the crippling symptoms.* Female, 74 years; gout, diabetes and "rheumatism" a frequent story among her immediate ancestors. She had an acute nephritis in 1882, followed by repeated attacks of gout from 1883-1890, and had been subject to a so-called "gouty throat" during her youth. For many years she had had repeated attacks of myalgia and nodes had gradually developed upon her fingers.

Arteriosclerosis had existed for more than ten years and a good deal of disturbance with her digestion for about six years. For the past ten years nervous symptoms, neuritis, weakness and disability combined to make her a partial invalid, but in 1912 when first seen by us a subacute, but slowly progressing arthritis of both knees was the striking condition. A course of treatment including massage at a European spa produced considerable improvement, but soon after her return home, the arthritis began to progress again, became acute, and finally almost completely disabled her. Despite frequent attention to her teeth in the past, she then showed a marked pyorrhea evidently of some duration and a culture from the pus pockets revealed a streptococcus viridans, but the complement fixation was doubtful.

Slow improvement followed dental surgery and the extraction of one of the most seriously infected teeth, but frequent relapses occurred, especially when the dental measures were not frequently renewed. However, persistent, thorough surgery, insisted upon by us despite the dentist's scepticism, aided, of course, by general measures, finally accomplished a complete and thus far permanent cure. The gratifying result is well expressed by a quotation from one of our associates who recently met her on the street: "She looked ten years younger, and was walking as well as I." When last seen, (ten months ago) she complained of dizziness and slight dyspepsia; reported that neither arthritis nor myalgia had recurred; that even the stiffness of her joints had disappeared many months ago and had not recurred; that she had required no medical advice but that she had had careful prophylactic treatment of gums and teeth every six to eight weeks. Her knees were then normal.

Routine Blood Examination.

Some doubt still exists as to whether the usual routine clinical examination of the blood and, in particular, the total and differential leucocyte counts reveal any characteristic departure from the normal of a practical diagnostic importance in oral sepsis. The almost constant accompaniment of complications, or of other diseased conditions in the patients under discussion as well as the variable state of activity of the streptococcus infection, militate against the possibility of clearing up such doubt.

W. H. G. Logan,¹³ in the examination of the bloods of 162 consecutive cases of oral sepsis, found that (1) anemia is not commonly associated; 2) leucopenia is more common than leucocytosis in pyorrhea where the pockets did not involve the root end; (3) leucocytosis is most commonly found with deep pyorrhea pockets; (4) leucocytosis was found in 47 of 52 cases of periapical infection without sinus, but leucopenia may occur in such; (5) there were abnormal findings present in 48 of 110 cases of pyorrhea examined. F. Hecker,¹⁴ in the examination of 250 blood films in pyorrhea, found the average differential count to be "polymorphonuclear 45 to 60 per cent., eosinophiles 1 to 3 per cent., mast cells 1 to 2 per cent., large lymphocytes 15 to 30 per cent., small lymphocytes 5 to 15 per cent., transitionals 1 to 3 per cent., and irritation forms of Ehrlich 3 to 10 per cent. He also believes the tinting of the nucleus and protoplasm of each cell is of especial importance.

A brief analysis of a few cases from our experience recently available for comparison in this particular has, therefore, seemed justified, especially so as most of the cases have been from the private practice of one of us, have been carefully studied clinically, and have been followed up for some length of time, painstakingly, and skillfully examined and treated, and the sepsis cured or very much improved by no less competent an oral surgeon than Dr. A. H. Merritt and his associate, Dr. Van Winkle. The blood examinations were all made by one of two observers, Bradbury or W. H. Ordway, Jr. The average figures for the normal leucocyte and differential counts of adults may be struck from the following figures selected from

We have not considered any count abnormal within the following extremes: total leucocyte 6,000 to 10,000, polymorphonuclear neutrophils 55 to 75 per cent., eosinophiles 0.5 to 6 per cent., basophiles up to 2 per cent., lymphocytes 20 to 40 per cent., and large mononuclears (includes transitional) 1 to 8 per cent.

Of 55 carefully studied cases of oral sepsis from private practice we have selected as available for analysis of the blood findings 25 cases, the others being excluded because of some important pathological condition other than the oral sepsis.

The hemoglobin, estimated by Sahli's instrument, in the twenty-five cases averaged 97.2 per cent., with a maximum of 120 per cent., a female with pyorrhea and gastric symptoms; and a minimum of 70 per cent., the only one below 85 per cent., a young woman of gouty antecedents, with chronic tonsillitis, arthritis, eczema, debility, and neurasthenia. In only three other cases was the hemoglobin below 90 per cent. These were women, one with bronchitis, another with nephritis, and the third with neuritis, cardiac hypertrophy, and a very marked pyorrhea.

The red cell count was determined in but nine cases and averaged 5,153,888, with a maximum of 5,700,000 and a minimum of 4,192,000. Including the latter only three counts were below 5,000,000: one in a woman with chronic nephritis and cardiac hypertrophy; another in an elderly male with pronounced arteriosclerosis, arteritis obliterans, and a very severe pyorrhea, and the third a woman with general debility, a prolonged neurasthenia and a very chronic but recently successfully treated antrum infection.

In this small series at least, oral sepsis in itself can hardly be credited with having produced any striking change in the hemoglobin or in the number of erythrocytes.

TABLE V—25 CASES OF ORAL SEPSIS

Dental Diagnosis.	Red Count	Hgb. %	Lots.	P.	L.	M.	E.	B.

m Pyorrhea	4720000	90	12600	77.0	18.0	3.0	2.0	...
n Inf. partially erupted tooth		70	9600	81.0	14.0	5.0	...	...
o Pyorrhea	5755000	110	8700	54.7	34.7	7.6	3.0	...
p Non-vital teeth, neg. x-ray	5628000	88	7800	73.0	21.0	3.0	...	...
q Pyorrhea, abscess		85	6600	58.5	38.5	0	2.0	1.0
r Exposed pulp	5040000	105	8000	75.5	13.5	6.0	5.0	...
s Gingivitis		94	6600	65.5	34.5	0	0.5	...
t Root abscess		100	9200	73.0	25.0	2.0	...	...
u Root abscess	5370000	120	9600	56.0	32.0	9.0	3.0	...
v Pyorrhea, gingivitis			7200	63.0	33.0	3.0	1.0	...
w Unsanitary bridge		106	6400	59.0	39.0	2.0	...	...
x Root abscess	4192000	100	3520	60.0	33.0	3.0	3.5	0.5
y Gingivitis, non-vital tooth		100	8200	69.0	26.5	1.5	1.5	1.5
Averages	5153888	97	8096	65.8	29.2	2.8	1.9	0.2

The average leucocyte count was 8,097. In but two cases were there more than 10,000 cells per cubic millimeter; a young man (10,800, 59 per cent. polymorphonuclears) with a gouty ancestry and a coexisting chronic tonsillitis, but with one of the worst and most obstinate cases of dental sepsis in our experience; the other, an elderly male (12,600,

77 per cent. polymorphonuclears) with the arteritis obliterans mentioned above. The only other patient whose polymorphonuclear count exceeded 75 per cent. was a young woman (81 per cent.) with a gouty ancestry and a coexisting tonsillitis. The only total count below 6,000 was 3,500 (60 per cent. polymorphonuclears) in a woman with antrum infection.

These twenty-five patients were all adults and although their average age was above 40 years a relatively high percentage of lymphocytes was found in many of them.

General Conclusions.—1. Even with an imperfect antigen the results of a complement fixation test for streptococci in the oral sepsis complicating or causing many forms of chronic invalidism, supports in general the clinical evidence of the etiological, prophylactic, and therapeutic importance of this organism, and emphasizes the desirability of further attempts along this line to assist diagnosis.

2. In twenty-five cases of pronounced oral sepsis the only suggestive feature exhibited by a routine examination of the blood is a high normal lymphocyte percentage, which, however, is certainly no more striking than in any collection of patients who consult a physician for some minor ailment.

RADIOACTIVITY IN THERAPEUTICS.*

By JOSEPH B. BISSELL, M.D.,

NEW YORK.

VISITING SURGEON ST. VINCENT'S HOSPITAL; DIRECTOR AND VISITING SURGEON, BELLEVUE HOSPITAL, NEW YORK.

THE action of radium depends upon many different and sometimes unstable conditions; radium in itself is a new therapeutic force whose powers upon living human tissues are still more or less unknown, not only to the general practitioner, but also to the expert radium therapist. The effects obtained by using radium are not limited to that peculiar phenomenon called radioactivity; radioactivity means the power of spontaneously emitting radiation which is possessed by certain elementary bodies. We call these radioactive substances, many of which have been isolated. Among them are ionium, thorium, uranium and radium.

Besides emitting rays powerful enough to penetrate through iron a foot in thickness and through the human body, they also give off energy in enormous quantities. For instance, an ounce of radium gives off in its transformation enough energy to lift 5,000,000 tons 30 feet. If this power could be utilized, what a wonderful agent it would make.

According to the physicist, energy is set free by radioactive changes exactly as it is set free by steam changing to water or water to ice, molecular physical changes. In chemical changes there is an action between atoms of different elements, as for example in the combustion of coal and the vast series of possible changes which produce among many other things the various therapeutic coal-tar products. A physical change on the other hand is a rearrangement of the molecules. Radioactivity differs in action and effect from either of these properties. It is a disintegration of the atoms themselves, with the phenomena accompanying it. Proportionately there is an amount of energy evolved by this greater than is produced by any chemical change. The result is obtained, but its cause is not understood. It is one of the problems of the new chemistry. Substances with radioactivity charac-

teristics are named radioelements, of which thirty-four have so far been discovered. Radium and radium emanation are two separate and distinct elements, yet one evolves from the disintegration of the other. In chemistry and physics radioactivity produces many physical and chemical changes. For instance, under its influence water is decomposed into carbon, oxygen and hydrogen peroxide; carbon dioxide is decomposed into carbon, oxygen and carbon monoxide; oxygen is converted into ozone; iodine is liberated from solutions of iodiform; ammonia is changed to hydrogen and nitrogen, while hydrogen and nitrogen unite to form ammonia. Some of the physical alterations produced by the action of the rays are interesting. The most familiar is the phenomenon of phosphorescence, which in certain substances may be more or less permanent. This phenomenon is made use of in illuminating paints. The octohedral crystals of zinc chloride, for instance, in the presence of radium become phosphorescent and remain so. A very small quantity of radium is necessary. Some of my surgical friends are now experimenting in a mechanical way by means of the illuminating quality of various radioactive mixtures. The prominence of radium in chemistry is not due alone to the interesting properties just mentioned, but to the fact that radioactivity makes it possible to experiment with the individual atom. Practically the chemist is now able to handle and demonstrate the atom as an entity. By this means it has been discovered that one element can be changed into another and that chemical and physical alterations of substances are due as much to changes in the weight and valence in the different atoms and to nuclear changes as to molecular and atomic combinations. Naturally from all these actions in the chemical laboratory the biologist has learned something of interest. One most important fact is that the rays alter greatly the vital functions of the living cell both normal and pathological.

The action of radium is conditioned upon the different effects produced by the various rays. Roughly speaking, the gamma rays penetrate 100 times as deep as the beta rays, which in turn are 100 times more penetrating than the alpha. The beta are electrons; the gamma rays are fluid light of great velocity resembling the x-rays in some of their therapeutic attributes.

The amount of raying necessary to obtain successful results depends upon many circumstances such as the quantity of the rayage, the variety of the rays, the amount of the application, the type of radiation, the structure and vitality of the tissues to be affected, also the constitutional condition, mental as well as physical, of the subject himself. There are undoubtedly certain and definite regulations which if carried out will produce the expected results, as surely as two and two make four, but the rules which govern such actions are not yet clearly or satisfactorily defined. It may be assumed, however, that a patient who has been suffering for a considerable time from malignant disease, who has been operated upon several times, whose weight has fallen off, who has no appetite or digestion, whose vitality is reduced, whose resistance is almost nil, who is suffering from the toxemia of long continued absorption, and in addition has the

*Being in part a discussion of Dr. Howard Kelly's paper on "What We Can and Cannot Do with Radium," read at the Academy of Medicine, 17 West Forty-third Street, Monday, October 1, 1917.

mental depression due to this state, does not afford a favorable case for any therapy. This is true whether the remedy be radium or the knife. Unfortunately this describes the type of malignant disease most frequently referred for radium treatment. No wonder that failure is almost inevitable. Such a result is not the fault of this valuable remedy, but it is due to the patient's weakened resistance and toxic condition as well as to our lack of exact knowledge of the powers of radium and how to make use of them. It is not that radium cannot do the work but that we do not know how to make it act to the best advantage in the proper case. We don't know the rules of the game.

In order to make the best use of the therapeutics of this powerful agent, it is necessary that the chemist, the physicist, the biologist, and a pathologist familiar with the action of this element, with an exact knowledge of the results of radioactivity in its different types on various living tissues, work in conjunction with the specializing physician and surgeon. As a result of their combined knowledge and experience, the definite place of this remedy in the treatment of disease could be established. In spite of the defects in our therapeutic and surgical equipment in the crusade against illness and death, there are many brilliant cures and some of them follow proper radium work. If we will change our usually accepted definition of "cure" to one which I think more suitable, the ratio of recoveries will be materially increased. A patient may be considered cured when relieved of all signs, symptoms, and difficulties of the disease and when his health is restored to normal condition, no matter for how long or short a period. The cure remains until the death of the person or signs of a return of the disease appear. The patient after all is the one intrinsically to be considered. There is nothing in this definition in regard to a time limit, whether it be three or five or fifty years. Death from other causes without return of the cancer even one day before the three year or the five year or any other time limit, is a cure, for the disease not having returned he remains cured of it. For instance, supposing, for the argument's sake only, that a patient from whom a malignant growth has been removed will surely have a return within five years, but long before that period is over he dies from typhoid fever or of an accident, without the cancer reappearing; he is as certainly cured of the cancer as if he had lived many years without a recurrence. Relieving a patient of the certainty of death and restoring to him the uncertainty of life is a cure. This, however, is a digression.

Radium therapy impresses the profession in varying degrees, rising from absolute scepticism of its therapeutic capabilities to supreme faith in it as a great human benefactor. Its failures naturally attract more attention than its successes, in both surgery and medicine. An exact estimate of the value of any new remedy is not possible until time and experience have proven its uses. Too little or too much radium may account for failure in individual cases.

Not enough attention is given by the surgeon to the value of radium in prophylactic work in pre-operative and in post-operative conditions. Too much reliance is placed upon its curative powers

and not enough on its palliative capabilities in the late period of malignancy.

Radium emanation is successfully given internally in many diseases. Accurate dosage and technique, knowledge of the characteristic action of the rays, of the amount and density of the necessary fillers, of the structures and tissues to be treated, as well as careful consideration of the vulnerability of the patient, are absolutely essential if one expects satisfactory results.

To particularize as to the lesions most amenable to radium therapy, there can be no question of its efficacy in certain benign and malignant skin lesions.

In relieving the skin cancers about the face radium is practically a certainty. This is fortunate, as in most neoplasms of this part of the body, the necessary surgical procedure is mutilating and leaves ugly deformities. Rodent ulcers are invariably cured if not too extensive, and even the larger ones are favorably affected if properly and persistently treated by radium applications. Neoplasms of the mucous surface of the lips and cheek have a high degree of malignancy and are an exception to this rule. Prophylactic treatment of suspicious growths or abrasions of the lip during the cancer age is advisable. Leucoplasia of the tongue responds favorably to scientifically applied doses of radium.

Recurring nodules in the skin following removal of cancerous breasts should always be treated by radium. If the treatment is persisted in with proper dosage, it is usually successful. Often the nodules absorb only under quite severe radium burns. Inoperable lymphosarcoma of the neck and mediastinum fortunately disappears quite often under heavy radium applications. The results in some of these patients treated by radium are so astounding as to be almost incredible.

In inoperative uterine carcinoma of extensive recurrence, radium offers practically the only hope. Where radium can be applied to the uterine canal in fairly large quantities, for a suitable period, where the immunological forces of the human tissues can still be stimulated, where the patient's resistance is not exhausted, and the toxemia is not too great, we may expect many favorable results.

Radium is very useful many times in cervical and uterine hemorrhages following recurring malignant ulceration; where pressure, styptics, and packing fail, radium in large quantity may produce thromboses of the vessels and thus check the flow of blood.

Brilliant results are obtained in the treatment of fibroids of the uterus by the use of radium. The symptoms improve, the tumors decrease rapidly, the menstruation becomes regular, and the patient is again a normal woman even to the extent of pregnancy if still in the child-bearing age.

Circumferential cancer of the rectum when inoperable is ideally located for treatment with radium, and numbers of such patients have been restored to health.

Striking cures of sarcoma of various types in the long bones are frequent in my experience. Notably a case seen with Dr. Sayre of spindle-cell

origin in the head of the tibia in a young woman, 22 years of age, and also one in a boy 18 years of age with a spindle-celled sarcoma of the femur, subperiosteal in origin, treated with Dr. Coley, are among the numerous ones in my recent practice.

The preceding cases are a few taken from the record book of the Radium Sanatorium. These results give sufficient evidence of what may be expected from the proper use of this remedy in selected cases.

46 WEST FIFTY-FIFTH STREET.

THE DIAGNOSIS AND TREATMENT OF OBSCURE CASES OF TUBERCULOSIS.

BY OWEN PAGET, M.D.,

FREEMANTLE, WEST AUSTRALIA.

MEDICAL OFFICER OF HEALTH OF FREEMANTLE.

IN an article entitled "Nasal Insufflations in the Diagnosis, Prognosis, and Treatment of Tuberculosis," published in the MEDICAL RECORD of Oct. 20, 1917, I described the utility of this method in the diagnosis and prognosis as well as treatment of this disease.

The average practitioner, although he is by no means ignorant of the prevalence of tuberculosis, finds the technical and indefinite methods of present-day diagnosis so complicated that he becomes indifferent to persuading his patients to have such tests applied, more especially when initial symptoms are only slightly referred to the chest and physical signs are obscure or absent. Further, he feels that when the case is diagnosed it is likely, either on his own advice or at the patient's request, to leave his hands to go to a sanatorium, as the results of home or office treatment are apparently dependent on quantities over which he seems to have too little control.

Now by my method of insufflations it is possible to regulate the disease whether in an acute or chronic form, and it is possible with certainty to predict that the varied and various symptoms will from day to day abate. Best of all, it eliminates the eccentricities of the disease and converts it into a complaint of a uniform and intelligible character.

But in this paper I want to draw particular attention to the utility of insufflations in diagnosis and show how they may assist the many physicians who are unable to draw conclusions merely from physical signs or indefinite symptoms.

The four following cases are perhaps of interest in this respect:

CASE 1.—Mrs. M., age 58, had borne five children.

Previous history: Indigestion as a young woman and body thin. Always liable to catch cold after washing clothes. Seven or eight years ago had a bad influenza cold with fever, and considers that from that time cough and trouble with chest started. Every following winter had a bad asthmatical cough. Anything would bring on an attack, which necessitated her going to bed on an average six months out of twelve.

Present condition: First seen June 20. Complains of a great deal of pain at pit of stomach, that she has no appetite, and, further, that if she eats she suffers from indigestion. Unable to sleep, and wakes up in the middle of the night coughing. Pain and tightness at midsternum, and she is shortwinded. Unable to do household washing. Coughs up much purulent sputum.

Physical signs: Dullness and weak breath sounds over back of right lung.

Treatment consisted of insufflations of tuberculin

B.E., the dosage of which varied from mgm. 1/12 to ¼ three times weekly in alternate nostrils. The patient attended at my office.

Aug. 12: Patient able to do her household washing and has not caught cold from it as formerly. General appearance improved. Has not been laid up in bed, though this is the severest winter for 45 years. Has lost dreadful feeling at pit of stomach and can take much longer and deeper breaths than formerly. No need now for sleeping draughts, as she can sleep well now all night, and does not wake up coughing and out of breath, as formerly, and unable to go to sleep again. Her children consider that she looks much better. Her appetite is good. Is keeping on the treatment without persuasion, although when first seen she said she was tired of doctors, chemists, and medicines. Has not been told that she has chronic tuberculosis. There is less dullness and improved breath sounds on right side. Sept. 1: Occasional coughs in daytime and a little sputum, which is, however, clear and watery. Her improvement is maintained. She has had some lumbago and rheumatic pains in joints. Although the weather has been very severe, she has not had to go to bed this winter in the daytime, and still attends at office, but only once weekly now.

CASE 2.—Mrs. H., aged 58, married, no children.

Previous history: Dates the commencement of her trouble 12 months back, when she went to live in a dark and gloomy house. Since then she has suffered from nervous depression, poorness of appetite with much pain and flatulence at pit of stomach, and also shortness of breath which is constantly increasing.

Physical signs: Weak breath sounds and dullness all over back. No cough. No sputum.

After a preliminary trial of stomachics and conventional lung remedies, which produced no practical result, treatment by insufflations was commenced on July 31. Patient's attendance at my office was somewhat irregular, but on Aug. 24 my note says: "Patient's appetite and flatulence much improved. Increased capacity to work and take deep breaths. She is in every way pleased. Sept. 1: Improvement continued. Able to carry on household duties."

CASE 3.—O'M., age 50, female; single.

Previous history: Bilious attacks with headaches since age of 14. Seven years ago suffered from a severe cold. Half-brother, who lives in the same house, is tuberculous. Two years ago she had to give up her business of dressmaking as she suffered severely from stomach troubles, such as loss of appetite and distaste for even the appearance of food, pains in the stomach both before and after taking food, and violent vomiting every morning. Has suffered from a severe cold with phthisicky cough for last six weeks. Had always been treated by medical men for the stomach. Did not consider there was anything wrong with chest except a little pain and tightness on left side.

Present condition: First seen July 16. Had brought up about a third of a chamberful of blood. More blood came with her cough. She was uncertain whether blood was coughed up or vomited. No examination made of chest on this date, but when it was examined some days later the physical signs were indefinite.

Treatment: Patient was given chlorotone capsules, grs. v, for sleeplessness, and phenacetine and caffeine tablets for intense headaches. Hemorrhages gradually quieted down, and on July 31 insufflations of mgm. 1/12 of tuberculin B.E. were commenced and given three times weekly in alternate nostrils. The dosage was increased from 1/12 to ¼ gradually. Temperature, which during daytime ranged from 100° to 99°, sank to normal about Sept. 9. Patient is of a very excitable type, with numerous friends, who by interminable conversation raised the temperature on occasions to over 101°. In spite of this there was a constant and steady improvement of all symptoms. Aug. 10: Headaches much better. No night sweats. Appetite good. Aug. 13: Cough not so frequent. Sleeping well. Aug. 19: Feeling very well. Sept. 7: Weak breath sounds and dullness at right apex and left base. Practically no cough or sputum. The patient at present, so far as headaches, appetite and sleeping are concerned, is in better health than at any time during the last two years.

The course which I intend to adopt in her case is a six weeks' further treatment and convalescence at

home, allowing her to get up gradually. After this she will go to the country for three months.

The importance of nose breathing is constantly impressed on her, but no props have been used.

CASE 4.—Mrs. N., age 41, two children.

Previous history: Indefinite history of pneumonia and pleurisy as a child. Five years ago, after birth of youngest child, pain developed in back and shoulders. Difficulty in talking, which brought on pain in right lung. First noticed catarrh at back of nose about this time. Has been to many physicians, who have given many opinions. Patient brought to me by husband, who fears she has tuberculosis.

Present condition: General appearance and appetite good. No cough or sputum. Suffers from pain beneath right scapula, which passes through lung to the front of chest. On physical examination apparently some dullness on right side back and front. The possibility of a hydatid was considered and an x-ray photograph taken with negative results. The only other symptoms are frequent headaches and catarrh at the back of the nose.

Treatment commenced on July 26 and consisted of biweekly insufflations of tuberculin B.E. at my office. Aug. 24: Headaches are somewhat relieved. Pain in chest is no better. As pain is apparently of a neuralgic character, akin to a girdle pain, patient has been given a sodium salicylate mixture, and insufflations have been discontinued. Sept. 9: Pain apparently relieved by mixture.

Diagnosis: If there is any tuberculosis in this patient's system, it is of so slight a character as not to require treatment. Her general condition is excellent and her pain is probably neuralgic.

As showing the advantage of my method in diagnosis, it is worth noticing that three out of these four patients ascribed their most distressing symptoms to the stomach. The patient with the hemorrhage had been treated by different physicians for some years for gastric complaints and neurasthenia. It is even more interesting to note that, except for a complaint of shortness of breath, these patients did not consider that there was much wrong with their chests. Physical signs on examination were also not very convincing.

That loss of appetite is so common a symptom early in tuberculosis is of considerable help in diagnosis, for improvement in this direction may be expected at the end of the first fortnight of treatment by insufflations. Such benefit to digestive tone not only confirms diagnosis, but encourages the patient to continue a treatment which is obviously beneficial.

But there are also other symptoms improvement in which show that our diagnosis is correct. A surprisingly common one is sleeplessness, and this not merely as a result of cough. In many of my cases I commence by prescribing in addition to the use of insufflations one or two 5-grain capsules of chloratone at night if required. The patient is told to leave off taking them as soon as possible, and this they usually do in two to four weeks.

Headache again is a symptom the relief of which by insufflations confirms diagnosis. In my work on tuberculosis this question of headache has perhaps given more trouble than any other matter. With a theoretical assumption that all the ailments of the nose and chest could be beneficially influenced by establishing a proper circulation of air through the nose and proper nose-breathing, I was at first much surprised that this gave but little if any relief in the headache of tuberculosis. And since my technique was very faulty in my earlier cases, I was inclined to consider that the application of sun-dried sputum or dead tubercle bacilli to the

nasal mucous membrane actually produced headaches. It is more than possible that this is the case when using such bulky products as I then employed.

The very mass of the vehicle, such as sugar of milk, may clog the openings of the sinuses. But if minute quantities of powder are employed, and my present method is to divide one 1 mgm. tuberculin B E tablet into eight, ten or twelve powders, thus giving doses of 1-8, 1-10, 1-12 of a milligram, then there is no question but that they actually and distinctly relieve and ultimately dispel the headaches. One of my patients, who had been in the habit of taking five or six phenacatine and caffeine tablets daily, in three weeks' time dropped their use entirely.

Without desiring to theorize too much, it is conceivable that nature congests the nasal mucous membrane and sinuses with blood and lymph in order to draw from them all the available antibody. If this is quickly and easily produced, then the necessity for the congestion ceases, and no headache appears.

In my former papers (references below) much stress has been placed on the necessity for the use of props to ensure nasal respiration, and this I consider essential in so far as regards the establishment of a permanent immunity. Up to quite recently I have also always employed them in treatment, as otherwise I feared that congestion and inflammation of the nasal sinuses would occur, but their necessity is not absolute. In only one of the cases cited above were props employed during treatment, and in this case really on account of post-nasal catarrh. I shall, however, impress upon all these patients the necessity of using props to ensure immunity in the future, unless they are able to educate themselves to nose-breathing, a very considerable difficulty, if not impossible at their time of life.

Anemia is another symptom the relief of which helps to establish a diagnosis. Unfortunately I have no blood tests to confirm my opinion, but facial appearance is very distinctly benefited. The muddy, sallow look so commonly seen in the chronic semi-invalid tuberculous patient is replaced by a skin of healthier tone and color. In acute cases the hectic flush is reduced to a pallor, such a pallor as is seen in the convalescence from any severe fever, and this in its turn is replaced by a skin of normal appearance.

The fact that nasal insufflations not merely relieve but abolish night sweats is not of course of great value in diagnosis, for as a rule with such a condition the diagnosis is already made.

Some relief to tubercular malaise may, like the improvement in appetite, be noticed at the end of a fortnight. It is not, however, an unmixed blessing, especially in the over-energetic type of tuberculous individual, since it leads him to believe that he is much better than he is and by over-exertion to bring about a relapse. I am in the habit of telling my patients that they should never try to do more than one-quarter of what they think themselves capable.

The ability to take deeper breaths and better to fill the chest with air is also an aid to diagnosis. This may be expected any time between the second

and fourth week. It can be confirmed on physical examination by signs of drying in the chest and improved breath sounds.

It is clear that my method of diagnosis by nasal insufflations is continued as a method of treatment, and since symptoms are certainly and definitely relieved and the disease controlled, the question of permanent cure must be considered, if only from a theoretical standpoint.

Practicing almost entirely as a surgeon, I was inclined at first to take, both on theoretical grounds and as the result of experiments, an extremely rosy point of view in this matter. But a longer experience and discussion with clinicians expert in tuberculosis work, though it has not diminished my beliefs, has yet enabled me to appreciate their scepticism, the result of many years of observation. A tuberculosis physician of high repute in America expressed to me the opinion that the question of cure could hardly be solved without a series of 5,000 cases which had been under observation for a period of at least ten years. Such an undertaking is of course impossible for the individual and is not within the province of the research-worker.

The question of the cure of tuberculosis is an appreciation of the factors controlling it, and of these the most important is the subject of this paper, namely "early diagnosis." Analyzing the cases mentioned shows that all are past the prime of life, and the average period during which it is certain they have suffered from tuberculosis is not less than five years and almost certainly more, when the indefinite character of the initial malaise is taken into account.

All these patients, though past the recuperation period of life, and with systems soaked, if one may use the expression, with the causative factors and products of the disease, are yet able in a really short space of time to show most definite improvement, sufficient, in fact, for them to carry on their ordinary duties.

From a diagnostic point of view it is worth noting that, though they had consulted many physicians, tuberculosis had never been diagnosed.

Pathologically, of course, these patients are not cured. There is for certain an enormous amount of fibrosis, which is unalterable, especially at their age.

Clinically they may relapse because they are certain to be careless about nose-breathing, and though feeling well and even free from physical signs, they may yet have many unhealed foci of disease. But to show that it is reasonable to be optimistic, I will cite the case of my original patient, who was treated with sun-dried sputum. Four years ago he appeared to have but a short time to live. Regarding the case as hopeless, I asked him to make the experiment of sniffing his sun-dried sputum up into the nose. At the present time, though over sixty, he has obtained a good position and looks better than I ever saw him before. He takes, however, great pains to breathe through the nose.

Assuming that in the future physicians give credence to my theories, and take the same interest in the nose of the adult as they do in children with postnasal growths, then it is possible to hope that cases of anemia and malaise in young adults will

be diagnosed and treated by my method, even before there are any physical signs.

And it is not merely a question of stopping at treatment, but just as in children we operate for postnasal growths, so in young adults we shall either by operation, the use of props, or education in nasal breathing be able to maintain a permanent immunity.

The outlook to me, not merely from theoretical consideration but from practical observations, is so hopeful as to make me believe that the whole question of the prevention, the treatment and the cure of tuberculosis is solved. Early diagnosis is dependent on the general interest of our profession in these theories, and for the present, at all events, on an application of my method.

Although it is certain that with the progress of time better ways of treating tuberculosis will arise, yet I want to point out that insufflations fulfill the general requirements of an intelligent treatment. It is easily applied by any physician; it has a definite effect on the disease in all its stages and varieties; it can be used in all cases and produces definite results in all cases; its effects are such that all symptoms and not merely some are relieved, and it definitely brings down the disease to a quiescent stage within a reasonable period of time. There are no harmful complications, unless it is very improperly applied.

I must, however, utter a word of warning. This is not a remedy which, like diphtheria antitoxin, almost immediately dispels the disease, and on no account must the importance of rest, good food, avoidance of overcrowding, and depressing influences be forgotten. Above all things beneficial is rest in bed and sanatorium treatment, or at least a holiday after convalescence is really established. The pertinacity of patients should not permit them to get about too early or to override a physician's judgment, and all cases should be regarded in the same light as enterics. My own experience with treatment by insufflations is that the patients are calmer and more willing to follow advice than in ordinary circumstances.

A difficulty physicians may experience is to persuade their patients to have a series of insufflations to establish a diagnosis, and it is not always advisable to suggest that tuberculosis is suspected. Under such circumstances a little harmless subterfuge is allowable, and the patient can often be persuaded when told that the insufflations are for the relief of headache or nasal catarrh. If at the end of a fortnight the patient's condition is improved, there is not much difficulty in continuing the treatment.

A second attack in tuberculosis, though not necessarily an expression of unsuccessful previous cure, since the patient may be reinfected, is nevertheless positive evidence that he is not immune. In addition, therefore, to early diagnosis and treatment it is necessary to be able to establish immunity before discussing the word "cure." Hence the question how much value can be placed on the immunity produced by nasal respiration?

If in a patient already infected with tuberculosis it is possible by insufflating dead tubercle bacilli or, better still, Tuberculin B E definitely to improve the symptoms, there is obvious justification for stating that the nasal mucous membrane is capable of pro-

ducing antibodies. And it is almost certain that it is this constant production of antibodies through the bacilli of the air falling on the nasal mucous membrane, which enables some people to be immune from tuberculosis all their lives.

Nasal respiration is not, however, the simple process which many believe. I have dealt with this side of the subject fully in my Australian publications, but it may be as well to reiterate some of the conclusions arrived at.

It is all important that nasal inspiration take place along and through the upper area of the nose, that is in the region of the upper and middle turbinates. An individual with such a capacious nose that the air passes without hindrance almost straight through to the trachea and bronchi is almost as badly off as a person who with pinched nostrils is only able to breathe through the mouth. The passage of air in inspiration through the nose must be such that it is slowed down sufficiently for the contained microbes to be deposited on the nasal mucous membrane. Only in this way can a constant supply of antibody be furnished to the lymph and blood.

When the air contains an excess of microbes, the deposit may be in excess of the capacity to deal with it, and the condition known as a cold in the head is produced. During this time, which is probably dependent on many factors, the formation of antibodies must be in abeyance. Starting with a certain number of factors, an appreciation of which is best understood by reading former papers, it is possible to produce infinite variations. The more I study tuberculosis, the more do these variations coincide with the eccentricities of the disease.

From a practical point of view it is impossible by the use of insufflations for a period of six weeks to immunize a patient for a period, say, of a year. There may be a cumulative capacity, but in reality it is an essential that the supply of antibody be constant.

Clinical tuberculosis can, therefore, on theoretical grounds be produced, not only by invasion, but by a breakdown in resistance. Take, for example, a patient with tuberculosis in the system, who yet produces sufficient antibody daily to keep it clinically in abeyance. Such a patient has an attack of measles with its accompanying coryza and concomitant diminution in the production of antibody. The result is that the tuberculous focus breaks out, as it is no longer neutralized and held in check. Such an aspect of the subject has already been put forward in my paper "Autosecretion in the Treatment of Cancer."

Of course, by the use of insufflations of tuberculin B E it is possible at any time to temporarily raise the quantity of antibody produced, but most important of all is its normal constant production.

If a case of suspected tuberculosis presents itself, there are certain definite lines to be followed. 1. Its diagnosis. 2. Its treatment. Of cardinal importance in the latter is that the patient be restored to his normal condition, and this necessitates real rest after convalescence. To be content with less is to place the patient in a position of unstable equilibrium between his infection and his production of antibody.

His production of antibody under normal circum-

stances is almost certainly sufficient to immunize him from infection, but if he returns to arduous work or trying circumstances with unhealed foci of disease, then it is more than probable that his production of antibody will be insufficient for his requirements. The patient must be impressed with the importance of making a fresh start in life from a sound basis, and he may then truly expect a permanent immunity.

The methods of establishing a proper nasal respiration have been dealt with in former papers and need no further elaboration. By improving methods of early diagnosis, employing definite treatment, paying attention to the importance of a complete restoration to health, and by operation or props enabling a constant production of antibody, it is possible with a considerable degree of reason to discuss the reality of the cure of tuberculosis.

SOME OBSERVATIONS ON GALL-BLADDER DISEASE AND ITS SURGICAL TREATMENT.*

By MOSES BEHREND, A.M., M.D.,

PHILADELPHIA, PA.

SURGEON TO THE JEWISH AND MT. SINAI HOSPITALS.

It is well within the memory of many physicians present when gall-bladder disease was considered a medical condition. Operations were rare. This was due to the rather misunderstood symptom-complex of gall-bladder disease and the natural averseness of the physician to have these cases operated upon. A diagnosis was not positive unless the patient had one or more attacks of gallstone colic followed by jaundice. Jaundice is still believed by many to be a necessary confirmatory sign, but a study of the symptoms of the patients in the large clinics dispels this idea. Jaundice, in fact, is rarely seen as compared to the number of cases operated upon. A constant muddy or brownish complexion without any other symptoms is indicative of gall-bladder disease. I have noted a few cases of this type finally terminating in cholelithiasis.

It was also considered essential that the pain be at all times characteristic; namely, in the right upper quadrant, colicky in character, and radiating to the right shoulder. As a matter of fact, the pain is variable. More or less uncomfortable sensations

*Read before the Mount Sinai Clinical Society, November 20, 1917.

located in the epigastrium and referred to the back and the adjacent regions, a sense of nausea after eating, and eructations of gas may be referred to gall-bladder disease. Special note should be taken of these symptoms in a patient past forty, fair, and fat. A continuous burning pain in the epigastric region may be significant of gall-bladder disease. The patient may never have had any acute colicky pains and still harbor gallstones.

Thanks to the surgeon and the more refined acuity of diagnosis on the part of the physician, various stomach complaints are now referable to the gall-bladder. The surgeon has led the way for the clinician to perfect his ultimate disposition of the case. The living pathology as revealed by the surgeon at operation has been the means of making better diagnoses. Still mistakes are made.

The differentiation from duodenal ulcer and a high appendix is important, though one sometimes is absolutely unable to separate the two. In duodenal ulcer the diagnosis is usually easy on account of the hunger pains and their occurrence two hours after a meal. The pain, which is usually relieved by the taking of food, may awaken the patient in the early morning hours. A high appendix will defy the diagnostic ability of the best clinicians and surgeons. We have all erred in the differentiation of the acute and chronic affections of these organs. I can recall many cases where the abdomen was opened for gall-bladder trouble and a post-cecal appendix was found with the tip in the right upper quadrant. In either case no great error has been committed from the operative standpoint, as the incision must be high in both instances. Gall-bladder disease may be confounded with certain other affections of the abdomen. This possibility of error is well illustrated in a case recently operated upon. A young man, aged seventeen, complained of severe pain in the right upper abdomen directly under the costal border. There was rigidity in this area and the patient had a little rise in temperature. These symptoms subsided but returned again in two weeks. X-ray examination confirmed the diagnosis of gallstones. Operation revealed many enlarged glands in the mesentery and omentum varying in size from a pea to a walnut.

Gallstone colic will often simulate labor pains in the later months of pregnancy. In the early months the two kinds of pain can be separated, but in the later months, when the uterus is above the umbilicus, I have seen errors in diagnosis. It has been the peculiar experience of many physicians that gallstones have their inception during pregnancy. I believe this to be the result either of a toxemia, an infection, stasis, or a high cholesterol content. It is evident why four out of five women should have gallstones when we consider the factors just mentioned.

It has been conceded for some time that the cause of gallstones is an infection. The infective agents may be numerous on account of the many avenues of infection to which the gall-bladder may be open. One source that has received considerable attention is the appendix. An ardent advocate of this mode of infection is Dr. Deaver. The distribution of the lymphatics and often the close relationship of these viscera make inflammation by continuity and contiguity not impossible. One never finds a diseased

gall-bladder without a diseased appendix. There is only one flaw in the deduction that appendicitis is always the cause of gallstones; namely, the appendix may have been removed years before the gall-bladder symptoms. The other avenues of infection may be along the common duct and through the blood. That infection occurs through the blood is unquestioned on account of the relation of gall-bladder disease to typhoid fever, but I doubt that many cases of gallstones result from infection up through the common duct on account of the sterile condition of the contents of the duodenum.

As diagnostic aids the chemical, pathological, and x-ray laboratories have been invoked. The cholesterol test has been studied in the chemical laboratory and has been found of considerable use in the differential diagnosis. I have had no experience with this test, but I will give you the results of Prof. Hawk and Dr. Lindenbauer with the Autenreith-Funk test on the serum of the patient. In 100 cases of suspected gall-bladder disease operated upon there was a high cholesterol index in 98 cases, all of which revealed gallstones. Certain diseases, including severe diabetes, pregnancy, arteriosclerosis, syphilis, nephritis, and sapremia may cause a high cholesterol index.

The x-ray is an important adjunct but must not be relied upon to make a diagnosis. I would much rather prefer the statement of the general practitioner that he has seen the patient in an attack. I do not want to belittle the value of the x-ray, but I do not consider it an essential adjunct in making a diagnosis of gallstones. The greater the number of instruments of precision, the greater it seems to me is our diagnostic sense obtunded. But the layman is so well educated as to the possibilities of the x-ray that it seems an act of omission on the part of the physician if a picture is not suggested. Therefore in gall-bladder disease I do not consider it essential to take an x-ray but it is simply done to satisfy and allay the mind of the patient. A positive x-ray diagnosis is of some help, but a negative diagnosis must not be considered in deciding for or against operation in a case of gallstones. Only a few weeks ago we operated in this hospital on a woman with all the symptoms of gallstone disease, the diagnosis being confirmed by the x-ray. The operation sustained the diagnosis.

The pathological laboratory has taught us that bile in the great majority of cases is sterile. This is providential when one considers the leakage that at times takes place during operation on the gall-bladder and the ducts. It is a comparatively rare occurrence for peritonitis to follow leakage of bile.

The medical treatment of gall-bladder disease, especially gallstones, has been a failure. The various resorts to which these patients are sent may allay the symptoms for a while, due to a change in their dietary and mode of living, but eventual cure is unattainable. The traditional treatment of giving a pint of olive oil is still popular with the laity and profession. It is problematical if this does any good. It is solace for the mind of the physician that he is doing something for his patient. The various chologogues of the older physicians have been found wanting and the newer and later preparations heralded as a cure for gall-bladder trouble have also been found utterly inefficient.

The prolonged medical treatment of gall-bladder disease leads to changes in the pancreas, infection, carcinoma of the gall-bladder and pancreas, and secondary inflammation of the pancreatic lymph nodes causing that form of lymphangitis so well described by Deaver. Some cases of the tragic type of pancreatitis could be prevented by means of a timely operation on the gall-bladder. Diabetes may even be secondary to neglected cases of gall-bladder disease on account of the secondary changes in the pancreas. I recently operated on a woman seventy years old with gallstone disease who had 8 per cent. of sugar. It was thought by all those in attendance that there was some relationship between the gall-bladder disease and her diabetes. After operation the sugar disappeared but acetone made its appearance, and the patient died six days after operation. We were compelled to operate in this case on account of the excruciating pain which required at times a grain of morphine to relieve. The pain was due to a stone trying to force its way into the duodenum from a pathological anastomosis with the gall-bladder. The cystic duct in this instance was occluded and the gall-bladder was atrophic.

It is proven now that cancer follows the many slight traumatisms inflicted by gallstones. For this reason alone if for no other an early cholecystectomy is paramount. During the past year I have been compelled on three occasions to close the abdomen without giving the patient any relief, due to the presence of carcinoma of the gall-bladder, pancreas, or liver. Schroeder, quoted by Mayo, says that 15 per cent. of the patients with gallstone disease develop cancer.

The logical solution of the cure of gall-bladder disease is the surgical extirpation or drainage of the gall-bladder. Not so very long ago most gall-bladders were drained before the exact pathology and nature of gall-bladder disease was understood. The stand must be taken that a gall-bladder once diseased is always diseased. In this respect it is in the same category with the appendix.

Drainage of the gall-bladder is now limited to some forms of pancreatitis in individuals with continued fever without assignable cause, and in patients with upper abdominal symptoms especially referable to the gall-bladder, in the absence of gallstones.

There still seems to be some discussion in the current literature as to the propriety of performing a cholecystectomy in preference to a cholecystostomy. There is no doubt, however, in the minds of the surgeons who have watched the immediate and ultimate progress of patients where gall-bladders have been removed that the results were far superior to those in which the gall-bladders were simply drained. In cholecystectomy one avoids that long-continued drainage which is obnoxious to the patient and which requires no end of attention on the part of the nurses. Convalescence is quicker and the patients are undoubtedly more comfortable. Cholecystostomy has its field, but it is becoming more and more limited. Even in cases where there is evident change in the pancreas and a pancreatic lymphangitis is present the gall-bladder ought to be removed and the cystic duct drained. To drain the cystic duct is not as easy as draining the gall-

bladder, but to the experienced surgeon this is no obstacle. In 1914, according to Mayo, 83 per cent. of gall-bladder operations were cholecystectomies. At the present time it is about 98 per cent.

It is almost the invariable rule now of most surgeons to remove the gall-bladder in the presence of gallstones or disease of the mucosa of the gall-bladder. The strawberry gall-bladder is especially troublesome and ought to be removed.

In doing a cholecystectomy a somewhat oblique incision is made, beginning in the epigastric region, the anterior sheath of the rectus muscle is incised in a straight line, the muscle is separated in the same plane, the posterior sheath is incised, which leads one to the peritoneal cavity. Two large abdominal pads are placed over the stomach, transverse colon, and neighboring intestines. Two large Deaver retractors then make tension on the gastro-hepatic and gastrocolic omenta, exposing by this means the gall-bladder and its ducts. At this point there is at present a technical controversy as to whether the gall-bladder should be removed from above downward or below upward. I prefer to do the operation from below upward, beginning at the cystic duct, because the blood supply is at once attacked. A cystic duct forceps is now clamped on this structure, which is severed, and then the common duct is probed; if found patulous nothing more is done to it. If the cystic duct is not wanted for drainage it is ligated and another hemostat catches the cystic artery; the gall-bladder is now peeled off the liver, the cystic artery is tied, the bed of the gall-bladder is sutured and a drainage tube is placed at the site of the severed cystic duct to drain any accidental escape of blood or bile. The wound is then closed.

It does not consume any more time to do a cholecystectomy than it does to do a cholecystostomy, and the mortality is not so high in the former as compared to the latter operation. The great danger of doing a cholecystectomy is injury to the common bile duct. This ought to be a rare complication of the operation if one isolates the ducts well. Nevertheless this accident happens to the best surgeons. Sixteen months ago I did a choledochoduodenostomy because one of our best local surgeons destroyed the common duct. This case is the subject of another paper and will not be discussed at this time.

Adhesions following a cholecystectomy are more numerous than after a cholecystostomy. If at some later time the bile ducts must again be explored great difficulty is encountered on account of adhesions. On the other hand, the removal of the gall-bladder takes away an important landmark. This was formerly a pertinent argument against a cholecystectomy, but with our increased familiarity with the pathology following the removal of the gall-bladder the difficulty of finding the common duct has been minimized. Recently it was shown experimentally on animals that where bile was spilled in the abdominal cavity during operation adhesions were more numerous than when the operation was performed in a clean field.

The question of recurrence is an important topic in the present discussion as it is the one phase that interests the clinician and surgeon alike. The surgeon is held to strict accountability for this occurrence. It can be said without quibbling that after a

cholecystectomy recurrence of symptoms is far less frequent than after a cholecystostomy. Symptoms return after cholecystectomy in less than 2 per cent. of cases while cholecystostomy shows about 15 per cent. of recurrences.

A study of the anatomical arrangement of the ducts is important in cases of recurrence of symptoms. In the many twists and turns a duct takes at times a stone may lodge in its recesses and escape even the careful search of the operator. On account of these peculiarities the common and hepatic ducts ought to be probed carefully at every operation.

In conclusion, I think it has been shown that gall-bladder disease belongs essentially to the field of the surgeon.

That gall-bladder disease is due to an infection through the blood lymphatics and by way of the common duct.

That the various laboratories have been of great assistance to the physician.

That the operation of cholecystostomy is confined to a very limited number of cases.

That the operation of cholecystectomy is far superior in every respect to cholecystostomy.

1427 NORTH BROAD STREET.

INTERNAL SECRETIONS AND PEDIATRICS.

By A. HYMANSON, M.D.,
NEW YORK

STUDY of any work on endocrinology shows us that animal experiments and experiments with artificial gland extracts make up a very large part of the subject matter. There is relatively little on physiology and pathology, save theories, and this is especially true of the young child. Even when disease processes begin in childhood the patients usually present themselves at a considerably later period and most cases of clinical "infantilism" are necessarily reported during adolescence and maturity. Arrested development does not stand out conspicuously in the first period of childhood and the sexual gland activities are not in evidence until the beginning of adolescence.

The relationship between disorders of internal secretion and diseases and anomalies of childhood may be studied in a twofold manner. First we take the most conspicuous affections of this period and endeavor to connect them with defective or irregular action of the glands. Second, we take the leading glands and consider what kinds of disease might be determined by absence or disease of these bodies.

By the first method we take such great developmental affections as rickets and idiocy and, with certain exceptions, we do not find that the internal secretions are definitely implicated either directly or indirectly.

By the second method we find that absence or disease of certain structures causes definite diseases but these are either rare or occur, like endemic cretinism, only in certain localities.

It is evident that "freaks of nature," "curiosities of medicine," etc., as they affect young children are palpably due to a considerable extent to disorders of internal secretion. Here belong certain forms of dwarfism, gigantism, precocious puberty, etc. But it is also evident that in many common ailments

there is an endocrinic element even if this cannot be proved. The most striking assertion of endocrinologists is that many sudden deaths in childhood, irrespective of the particular disease, are really due to exhaustion of the adrenal glands, perhaps in association with the status thymicolymphaticus.

Apparently not a few cases of internal gland disease are secondary to local inflammations, etc., in which the gland is compressed or incited to overaction. This is often the case with affections of the hypophysis where any affection of the base of the brain could implicate the latter.

In the adult there is a recognized technique for examining the endocrinous system which is only partially applicable in the young child whose pilous, dental, and sexual apparatus is still undifferentiated. In regard to the congenital absence or removal of glands of internal secretion, only the thyroid and the gonads are available for study in man on a large scale, the latter because of the custom of castration in childhood.

Endemic cretinism is by no means directly due to loss of thyroid tissue but is a very complicated condition. Serious lesions of the endocrinous system affect the gonads secondarily. Metastases from mumps, etc., to the gonads practically do not occur in childhood. Very early castration of boys causes a form of infantilism from non-development of secondary sexual characteristics, but without true effeminacy. Early castration of girls has an analogous result, but in a certain number of cases masculine traits develop. In eunuchoidism so called the endocrine system may not be demonstrably involved, while in pseudohermaphroditism it is probably not involved at all. In very rare cases metastasis of mumps to the pancreas has caused destructive changes in the latter with diabetes.

In absence, removal, destruction, or disease of thyroid tissue we see the development of congenital and acquired forms of myxedema, which are so well known to pediatricists that a description is hardly necessary. It will suffice to state that in athyreosis and hypothyroidism we see arrested development of bones and external soft parts and impairment of the psychic and most of the somatic functions. The general result is one form of infantilism with muscular quiescence and mental apathy. Metabolism and thermogenesis are much inhibited, the latter in part because of the inactivity of the sweat glands.

Destruction of the pituitary body is usually followed by acromegaly but this sequence is not inevitable, for either affection can occur without the other. Conditions here, however, are far more complex than in the thyroid, because the hypophysis is apparently composed of three different organs, each with its own independent role. Hence the varying and bizarre results which follow overgrowth, hypoplasia, or stimulation of its tissues, from local factors; to say nothing of its inter-relations with other endocrine glands, and the possibility of involvement in a general infectious process.

Enlargement of the pituitary body during the growing period causes gigantism, enlargement after the cessation of growth causes acromegaly. Hypopituitarism occurring early in life causes infantilism and dwarfism with arrest of sexual develop-

ment, with or without obesity, increased tolerance for sugar, etc. So called dystrophia adiposogenitalis is not regarded as an affection of childhood.

We have little exact knowledge of the thymus in man. After castration in both sexes it persists and may exercise some function. Its complete removal in animals arrests the development of the bones. We know even less of the parathyroids in man. Their removal in animals quickly causes death from convulsions (tetany).

We may consider endocrinology from the special viewpoints of the neurologist, the pediatrician, the specialist in internal secretions, and the therapist.

The neurologist seems to regard the subject as **belonging especially to his province**. The reasons are not far to seek, for two of the important structures are seated within the skull (hypophysis and pineal gland), while tetany and other motor disorders appear to stand in some relation to the parathyroids. Perhaps the most weighty reason, however, is the fact that thyroid insufficiency and to a certain extent underfunction of other glands are so closely associated with arrest of mental development. Hyperthyroidism in its more pronounced forms is also regarded as a neurosis. In the recent work of Jelliffe and White on diseases of the nervous system, the endocrinopathies are discussed exhaustively in the early chapters as part of the necessary foundation of neurology; but aside from cretinism and myxedema it does not appear that child pathology plays a very extensive role.

Neurological journals contain a considerable literature on endocrinology, very largely in connection with the mental characteristics of dwarfism, infantilism, and eunuchoidism. Weygandt¹ shows, however, that endocrine disorders form only one factor among the causes which combine to arrest the development of body and mind. On the other hand, with pronounced lesions or anomalies of these bodies, the mind may be normal, *i. e.*, it may not share in the somatic disturbances.

It is evident that many kinds of anomaly of growth and development, while showing pronounced individuality, are yet closely related. These may stand in relationship with glandular structural or functional anomalies, or the endocrine bodies may not be involved at all. Aside from infantilism of several distinct types, dwarfism, and eunuchoidism, there are child senilism, mongoloidism, the hypoplastic constitution or status thymicolymphaticus, dystrophia adiposogenitalis, and so called pluriglandular insufficiency. Starling² describes numerous cases of eunuchoidism, several of which were seen during childhood.

In Aschaffenberg's "Handbuch d. Psychiatrie," the volume on imbecility and idiocy (1915) is devoted very largely to affections due to anomalies of internal secretion. Wagner von Jauregg writes at great length on myxedema and cretinism, while Weygandt discourses extensively on what he terms glandular infantilism. The latter includes the status thymicolymphaticus and thymic idiocy, dysthyroidism (myxedema, hypothyroidism, Graves' disease), dysgenitalism (gigantism and obese states), dyspituitarism (acromegaly, dystrophia adiposogenitalis), dwarfism of hypophysis origin, and disturbances of the pineal gland.

A special section is devoted to pluriglandular affections. In some conditions we see defect in certain organs with compensatory overaction of others. In real pluriglandular insufficiency, however, there are defects of a number of the endocrinous glands, so that we may see side by side hypothyroidism, hypopituitarism, and some of the phenomena of Addison's disease along with secondary hypoplasia of the genitals. In these pluriglandular cases arrest of mental development or a form of infantilism may coexist. If idiots and backward children in institutions are closely studied we may find evidences of pluriglandular insufficiency in a certain number and it is in such cases that some hope of relief may be held out.

Not only may thyroid medication alone be of use but there are remarkable cases on record in which pluriglandular therapy has produced astonishing success. Cases of this type were reported by Dupuy in 1912. The type of case to benefit most was that of slightly backward children of dwarfish stature and disproportion, hypoplasia of the sexual organs, troubles of dentition and ossification, general hypotonia, and defective circulation. The therapy comprised thyroid, hypophysis, and suprarenal extracts with testicular or corpus luteum extract in certain cases. Excellent results were obtained in 22 cases. The only drawback from the pediatricist's viewpoint is that these subjects had largely passed into the period of adolescence. One girl of 14 showed very remarkable improvement in growth, height, mental state, and general health.

If we glance through any modern work on pediatrics—for example, the latest edition of Holt (1916)—we shall find full descriptions of sporadic cretinism due to congenital absence of the thyroid and of the acquired form of infantile myxedema, also termed hypothyroidism. These conditions are well recognized and well known to the pediatricist, and need not be detailed here. We shall also find good accounts of enlarged and persistent thymus and status thymicolymphaticus, and mention of the fact that this condition stands in close relationship with fatal convulsions and sudden death under all sorts of conditions. We are, however, unable to explain this relationship, nor is there any way in which we can proceed against this condition save by surgical removal or perhaps the *x*-rays. The frequent association of enlarged thymus with rickets and the fact that a condition resembling rickets follows thymectomy in dogs do not necessarily prove anything. Pediatricists admit that while the parathyroids probably have something to do with the production of tetany and perhaps other spasmodic affections, the role is not a major one, and, further, parathyroid substance seems to have little or no influence over tetany.

Graves' disease is admittedly very rare in childhood, but according to Holt some degree of hyperthyroidism is very common, especially in girls from 8 to 15. There is no exophthalmos and the pulse may be but slightly accelerated, with a tendency to palpitation. The children are active, restless, irritable, and emotional, with moist hands. The thyroid body may show very slight enlargement. As a rule the condition is outgrown.

There are numerous complicated conditions associated with arrested growth and sexual development

and at times with accelerated growth and precocious puberty in which several of the endocrine glands are doubtless involved. Here belong cases of so-called infantilism in which as a rule implication of the glands cannot be demonstrated. In certain cases there are growths implicating the hypophysis, pineal, or adrenal glands. But tumors of these organs do not necessarily give rise to these disease pictures. It is probable that in endemic cretinism several glands are involved.

It is well known that a number of clinicians have advocated that diseases of the glands of internal secretion be made a separate branch of clinical medicine. Dr. Sajous, the dean of these men, would term this specialty hemadenology. Quite recently a society has been formed to push the development of this line of activity and during the present year a new quarterly periodical named *Endocrinology* has seen the light. In the July-September number of this journal we find editorial matter devoted to the subject "Present-Day Endocrinology from the Standpoint of the Pediatrician." The editor states that no specialist can be more interested in endocrinology than the pediatricist and cites four points of interest, as follows: cretinism and myxedema are associated with the thyroid; spasmophilia with the parathyroids, inspiratory stridor and sudden death with the thymus, and collapse in diphtheria, etc., with the adrenals.

On the other hand the results of study of the immense literature are disappointing. Autopsies frequently show that supposedly diseased endocrine glands were normal. Some would make internal secretions responsible for almost the whole of pathology but if the entire literature for a year were boiled down and distilled there would be little of value to add to the sum of our knowledge. Great emphasis is laid in the negative results reached by Hammer after a most exhaustive study of the thymus. By counting all the Hassall's corpuscles in a gland he proved that size bears very little relation to the actual amount of parenchyma. Variations of the latter could not be associated with general anomalies, but an enlarged thymus may cause much local mischief as a mechanical nuisance. While the editor is naturally optimistic about the future practical value of his subject he calls for more facts and less theorizing.

Let us now take up the subject of endocrine therapeutics, the rational use first, followed by the more or less empirical employment.

It does not appear that we have more than one form of rational and dependable organotherapy in this branch of clinical medicine; to wit, the use of thyroid preparations in congenital and acquired myxedema. Bramwell apparently cured a case of so-called pancreatic infantilism, a very rare affection, with pancreas preparations. But in a single case we cannot be sure that the improvement was not spontaneous. We may feel assured that so-called hypothyroidism is a *bona fide* condition, due practically to deficiency of thyroid tissue and always to be benefited greatly by thyroid treatment. The result is not only fairly constant but is usually promptly seen. If the use of the drug is intermitted we see a relapse. In no other single gland of the body do we see analogous behavior—in neither the thymus, parathyroid, hypophysis, suprarenal, nor pineal. In cases in which there is a probable general disorder

of the chromaffin system thyroid medication is rationally indicated, with or without other preparations, because of the part played by this gland in regulating the action of the others.

Empirical therapeutics must be kept distinct from the rational use of these preparations; for if a given condition improves under thyroid medication this does not mean that it was due originally to thyroid insufficiency. In certain cases the character of the improvement suggests that the morbid state could have been due, in part at least, to insufficient action of a given organ, but in other instances no theory can explain the results. No one really knows why thyroid medication can cure bed-wetting in children. Hypophysis extract has apparently prevailed over such conditions as rheumatoid arthritis and rickets in childhood. Suprarenal extract is said to be of value in cyclical vomiting of childhood and also in certain cases of backwardness of growth and development associated with weak muscles and sluggish minds. Croftan claimed that he obtained good results from pancreas extract in diabetes of childhood.

A good account of endocrine medication in childhood is given by Waller³ as follows: "Thyroid remedies have an inconstant action and while small doses often help nocturnal enuresis large ones may aggravate it. But it will not do to say that nocturnal enuresis is due to thyroid insufficiency. The thyroid substance probably acts on the pituitary or adrenals. Thyroid extract is often of great value in urticaria in children, especially when chronic. At the same time it can cause urticaria. The extract probably activates some gland which controls calcium metabolism. Even in cretinism the action of the thyroid in provoking growth should be related to its power over calcium metabolism, especially in the long bones. Thyroid treatment will render acid saliva alkaline and perhaps indirectly ward off dental caries, while excessive doses have the opposite effects. Thyroid substance in excess can cause tetany; while in small doses, perhaps by its action in promoting calcium metabolism, it acts as a nerve sedative in tetany and epilepsy. Thymus extract in theory ought to be of value in phosphorus metabolism and also calcium metabolism, because most of the calcium in the body is present as phosphate. In prescribing for children it is well to use several extracts at once. Thyroid and suprarenal extracts often give better results than thyroid alone. The author believes that excitable, nervous, energetic children owe this disposition to slight overproduction of thyroid. The latter is apt to render subjects wakeful. Thyroid extract is of great value in convalescence from the diseases of children, especially when they do not eat well. It is often of benefit in both diarrhea and constipation."

Dr. M. B. Gordon⁴ also gives a good account of organotherapy in childhood. The thyroid gland is, of course, a specific for myxedema and sporadic cretinism, as regards both the physical and mental symptoms. The degree of thyroid inadequacy may range from such pronounced conditions to single and mild phenomena of hypothyroidism. Under the latter head the author includes tiring easily, slight puffiness of the eyelids and face, and pigmentations of the skin; all of which may respond to thyroid medication. A cold skin and sluggish circulation may also be classed here; and there is evidently a thyroid factor in cases

of eczema, psoriasis, and scleroderma. In children with hereditary syphilis, a condition noted for its action in arresting growth and development, he has found thyroid substance of value. Even in rickets and convulsions the same treatment is occasionally followed by remarkable benefit. Chorea and asthma are sometimes favorably influenced. But caution must always be employed while giving thyroid preparations, for there is sometimes an idiosyncrasy against them and they are expressly contraindicated in circulatory diseases and diabetes. Like Waller, the author finds the tendency to produce the very affections which it relieves. Parathyroid extract, while hardly a specific, seems to be of occasional value in motor disturbances (tetany, chorea, convulsions). This remedy should be given only in hypodermic solution. Suprarenal extract is recommended in the acute infectious diseases of childhood with low blood pressure, especially diphtheria and pneumonia. However this is used only in the form of adrenalin injections and hardly belongs under organotherapy. Hypophysis extract has thus far hardly won a place in pediatrics.

The writer will conclude the article with a brief summary of his personal experience:

The internal secretions play an important part in the animal body but their real value in pediatrics offers a large field for investigation. No one will doubt the usefulness of thyroid in cases of athyreosis and hypothyreosis, but in the latter where the functional defect is very mild, the disease is quite often overlooked and treatment is begun quite late—naturally the result is not very encouraging.

Indiscriminate use of thyroid will certainly bring discredit on the drug. In a case of infantilism of the Lorain type which was under my care for several years⁵, I administered thyroid for about 15 months without any improvement. Quite often the drug had to be discontinued on account of gastrointestinal disturbances which it causes. Although the Lorain type of infantilism is not supposed to be affected by thyroid, still, Brissaud of Paris had found the thyroid rudimentary in one autopsy. I presume that in a case of this type where thyroid by mouth causes gastrointestinal disturbance, it is highly possible that transplantation of the gland might have been followed by better results.

The disappointment in the use of the drug is at times due to an improper dose. It is best to begin with small doses for an infant—one-fourth to one-half grain, twice daily, and proportionately larger doses for older children—to be increased every two or three days until five or even eight grains are given t.i.d. The amount ought to be increased to the point of toleration, and then reduced again. The drug must be administered for years, otherwise the patient may deteriorate.

As to the maximum dose of thyroid an interesting case is related by Dr. A. Jacobi.⁶ In a cretin six years old under hospital treatment, he was obliged to increase the dose of thyroid to 36 grains per day, which was taken for several days without signs of thyroidism. When the maximum dose was reached the general improvement was rapid.

I have seen good results in thyroid treatment in small doses in cases of malnutrition, which was perhaps due to hypothyroidism. In severe cases of the exudative diathesis of Czerny, accompanied by a

severe eczema, particularly in very stout children, which did not respond to diet and ordinary medication, the improvement was rapid within a few days of administration of the drug.

Epinephrin I have found very efficacious in nephritis following acute infectious disease, particularly scarlatina nephritis.

Pluriglandular insufficiency deserves special consideration. Pineles's suggestion that there is a relationship between the various ductless glands and that at times more than one organ is altered in function and perhaps in structure, has been proven to be correct. The empirical treatment with polyglandular extract has certainly done much good in many a case of this sort.

In severe cases of rickets, where no improvement was shown by change of diet and prolonged use of usual remedies, marvelous improvement and even cure has followed the administration of small doses of thyroid extract in combination with pituitary extract. It is strange that treating these cases with thyroid alone or pituitary alone, did not show much improvement. I will cite two cases of the many that have come under my care.

Alice D., 12 years old, after a severe attack of mumps, became peculiarly nervous. She became cranky, somewhat stupid, did not get along well at school, complained of a tired feeling, stopped growing, and became very stout. I saw her a year later when she was 13 years old, and found that her hair had become somewhat coarse, and her skin, which was very supple before the sickness, somewhat hard. The menses were absent. Her weight was 125 lbs., height 58 inches. Urine acid, blood normal. She complained of general debility and pain in the ovarian regions. I thought that the attack of mumps might have affected her thyroid gland so I gave her thyroid substance for about 4 months.

Although she lost about 10 lbs., her general condition did not improve, nor did she grow. I lost sight of her for about six weeks. On her return from the country, after a careful examination, I found that the case presented symptoms of polyglandular insufficiency; the dry skin, coarse hair, and adiposity were due to hypothyroidism; the pain in the ovarian region was from ovarian insufficiency; the stoppage of growth was perhaps due to hypothyroidism, the stupidity to the pineal insufficiency and the asthenia to adrenal trouble. I then combined all these drugs, and after administering them for two months there was a marked improvement.

After 10 months of polyglandular treatment she gained 2½ inches in height, her menses began to grow, she began to menstruate regularly, her hair became soft, her skin supple and she was much stronger and brighter.

A case of acromegaly with some myxedema and albuminuria was described by me some time ago. The patient has been under my care for about 23 years. I continue treating her intermittently with thyroid, pituitary extract and at times epinephrin and it seems that her ailment is not progressing. She always feels much better when she takes the drugs, and claims that these capsules relieve her headache immediately.

Military Medicine.

SANITARY FUNCTIONS OF THE ARMY SURGEON.

THE army medical officer, like the sailor, must be a handy man. It is not enough that he is able to treat disease and wounds after the most modern and approved methods, but he must be fully competent as a sanitarian and hygienist. In fact, it may be said that in a general way his capabilities in this direction are of even greater importance than his skill as a surgeon or physician.

An epidemic of disease will quickly kill or incapacitate more men than shells or bullets, and it is safer by far to prevent disease than to attempt to cure it. Therefore, the military surgeon should have a thorough practical knowledge of sanitation and hygiene, or he will not fill his position effectively. Among the duties which fall to the lot of the surgeon of the regiment, as pointed out in the report of the Surgeon General of the Army for the fiscal year 1917, are the enforcement of the maintenance of thorough camp policing, of prompt and effective disposal of refuse, of the destruction of flies, and of the proper sanitary condition of the latrines and bath houses. He must see to it that the men keep as clean as possible. This insistence upon personal cleanliness is not for esthetic reasons, but because it is now recognized that a large proportion of the contagious diseases are transmitted by personal contact, and because other serious maladies are disseminated by means of insects which live on the human body. Personal cleanliness does not consist only in keeping the body clean, but in keeping the mouth, nose, and throat in as aseptic a state as possible. It is obvious that it is extremely difficult under existing conditions of warfare for men to keep even moderately clean, and one of the hardest problems to solve at the various fronts in Europe has been to provide washing facilities, or rather disinfecting facilities, for those who have been living in the trenches for two weeks or so. However, it is an important function of the army medical officer to enforce personal cleanliness on the soldiers of his command. Army regulations require that each man shall wash his hands before each meal and immediately after visiting the latrine. That the hands and nails should be kept as clean as possible is most essential to health and to the prevention of infectious diseases, for hands carrying infective material are a frequent means of spreading disease. Careful food inspection is another important part of the army surgeon's duties, for carelessness in this respect will result assuredly not only in the spread of disease by means of food infected by insects, but will also cause gastrointestinal troubles.

The army surgeon must be a capable sanitarian and hygienist, and now that so many civil medical practitioners have taken military positions the need for including training in sanitation and hygiene in the medical curriculum has been amply demonstrated.

OTOLOGY AND THE WAR.

IN an instructive article on "The Prevalence of Ear Injuries and Diseases in the French Army," published in *The Journal of Laryngology* for November,

1917, Dr. W. Sohier Bryant of this city calls attention to the urgent need of an aural service in connection with the Army Medical Department. This has been foreseen, in a measure, by the alert surgeon-general of our army, and many otolaryngologists have been called upon for advice and for active service with the army in the field. Yet it may be doubted if even they, thus far without practical experience of war conditions, know how much they will be needed.

Dr. Bryant, now a major in the Medical Reserve Corps of the U. S. Army, has been on the other side for some time, in fact, since before we entered the war, and has made excellent use of his time in studying the conditions both at the front and among those evacuated to base hospitals. The observations which form the basis of the paper above mentioned were made last summer while he was temporarily serving in the French army as *médecin traitant d'otorhino-laryngologie*. His surprise was great to find such a large proportion of ear injuries and defects among the wounded, their number amounting to about the same as that of the ocular troubles; that is to say, six or seven times as many as might have been expected. In the "zone des armées," at the front, the percentage of ear cases in the evacuation hospitals was 16, and in the "zone des étapes," in the rear of the other zone, the percentage was 6.25, this figure naturally rising during periods of inactivity at the front, and falling during the active periods, when a large number of men with bodily injuries were received; in the interior, the ear cases formed 9 per cent. of the total sick.

The writer estimated that about 80 per cent. of these ear cases would show considerable impairment of function, permanently interfering more or less with the future civil occupations of the patients. This impairment of industrial capacity has a twofold bearing—the crippling of the individual and the increase which this will entail in the pension list. From the figures which he has gathered Dr. Bryant estimates that the allowance of pension claims for ear disabilities will amount to a minimum of 24 per 1,000 of the fighting force per year. The necessity, therefore, in the interests both of the individual and of the State, of a sufficient force of otologists in the medical corps is made very evident by Dr. Bryant's timely investigation. In former wars medical interest revolved around the treatment of the deaf soldier after he had left the army. Now, otologists among the Allies, especially the French, are striving to erect in the army itself a specialist organization for dealing with otolaryngology. Although much has been done in this direction, Major Bryant implies that much still remains to be done to cope with the tremendous increase in injuries, generally serious, to the hearing apparatus.

IS TRENCH-SHIN AN ABARTICULAR RHEUMATISM?

WHETHER the so-called "trench-shin" is really a disease entity or only a symptom of "trench-fever" is a question about which much can be—and has been—said on both sides. For example, McNee, Renshaw, and Brunt,* who were the first to publish a complete, accurate study of trench-fever, and

*"Trench Fever." By McNee, Renshaw, and Brunt. *British Medical Journal*, Feb. 12, 1916, p. 225.

Houston and McCloy,* who agree with them, hold that trench-shin is a symptom of it, while Chambers,† McLean, and others describe it as a separate disease. We cannot examine here the arguments advanced by these differing exponents, nor can we go at length into a description of the disease, but only mention briefly one ingenious theory advanced by Chambers, namely, that it is an abarticular rheumatism.

The pain of trench-shin is a dull, aching one, increased by any sort of movement, especially by walking; there may be pain also in any other part of the body, particularly in the back, and a characteristic feature of these pains is that they miss the joints, although they may be severe in the bony prominences around the joints. It is this peculiarity which has led Chambers to allude to it by the above name.

The points which harmonize to a greater or lesser degree with this viewpoint are the obscure etiology and pathology, the character of the pain, the moderate leucocytosis, and the redness and tenderness over the seat of pain. Against the classification of this condition as a rheumatism are the insufficiency of the evidence adduced and the resistance of the pain to the salicylates, aspirin, and phenacetin.

Interesting as the above question is from an academical standpoint, we should not forget that the disorder, whatever it is, removes every day numbers of soldiers from the fighting line and in some cases keeps them from active duty for many months. We have before us the more serious problem of etiology, prevention, and treatment, and we should not be led astray by the "labelling mania."

Some of the Limitations of Military Orthopedic Surgery.—In a paper read by M. O'Gorman Hughes of Sydney, at a meeting of the New South Wales Branch of British Medical Association on October 26, 1917, and published in the *Medical Journal of Australia*, December 1, 1917, the author said that he did not wish to appear as an apologist or as a pessimist, but two years' surgical work at No. 4 General Hospital had resulted in a certain amount of disillusionment. After reading the brilliant results of several orthopedic surgeons and especially the reported results of secondary nerve suturing, one was apt to think that given the material one had only to go and do likewise. We are, however, at once confronted with very different conditions from those ordinarily obtaining in civil practice. Sepsis has been the rule and if not apparently active, is often only latent and ready to recrudescence on the slightest interference. One can imagine weeks, sometimes months, of patient waiting till septic wounds are healed before one dares to attempt operative treatment, and later one can picture the despair of the patient and operator when sepsis spells failure. In the long bones pus cavities have been found three months after the wounds have healed, so that it is no easy matter to lay down definite rules for the length of time to wait before interfering. Another source of trouble is the great scar ring about many of the wounds, scars in the

skin, fascia, and muscle. These conditions not only render an operation more difficult, but obviously interfere with quick clean repair. The length of time spent in waiting before operating on nerves is a serious drawback, and in the meantime it is particularly essential to maintain the nutrition of the muscles, to prevent their lengthening and contraction, and also to prevent adhesions of joints and tendons. Unfortunately, in many cases this is very difficult and consequently subsequent treatment is increased. The following is a brief summary of some of the cases that have come under Hughes' personal observation.

Out of seven cases of arthroplasty for bony ankylosis of the elbow, the results were good in six. The remaining patient had a flail joint, owing to marked atrophy of the muscles about the elbow. In two cases bone flaps were used: that is a piece of the separated bone with periosteal covering was united by chromic catgut to the cut surface of the humerus. In both instances the bone flaps necrosed and had to be removed, but fortunately did not spoil the result. In the other five cases muscle flaps were used.

In nine cases of arthroplasty for bony ankylosis of the fingers a bone flap was used with one exception and the latter was the only case requiring a second operation. At the second attempt a bone flap gave a movable and useful joint. Most of these patients still require massage and movements. There was one arthroplasty of the temporo-mandibular joint, an excellent result being obtained with a flap of temporal fascia. We had three cases of bone grafting for defects of the mandible, tibia, and radius. On only one occasion when dealing with the radius was primary union obtained and a successful result.

Adherent scars of skin to muscle limiting movement have done well, sometimes after a simple excision and at other times after interposing a piece of fascia lata and fat under the skin. The fascia lata has a great capacity for resisting sepsis and remained in situ even when the wound suppurated. One of the best illustrations of this sepsis-resisting power was in the case of an old urethral fistula. After five failures at home and abroad to close it, healing readily took place when a piece of fascia lata was stitched over the opening in the urethra and the skin sutured, fascia lata was also very useful for repairing a gap of 7.5 centimeters in a flexor tendon.

In operating on nerves for paralysis, the results were brilliant. When the disablement was due to the pressure of a bullet and the latter was removed movements which had been absent for months could be readily, but somewhat incoordinately performed on the day after operation. Results were equally good but not so immediate, often freeing nerves from the pressure of scars or callus. In all cases where the nerve was found to be divided and the ends separated by scar tissue or joined in bulbous union, the ends were freshened and sutured. At all times it was possible to approximate the freshened ends with chromic catgut without undue stretching and only once did suppuration occur. Almost always the site of union was encased in a piece of fat. The limb was kept flexed for, at least, three weeks, and the

*Houston and McCloy. *Lancet*, 1916, Vol. II, p. 632.

†"Trench Shin an Infectious Fibrositis?" By Graham Chambers. *Lancet*, 1916, Vol. II, p. 752.

paralyzed muscles kept permanently shortened by suitable splints. The first operation was performed two years ago and the last three months ago. The operation has been found to improve sensibility to hard pressure in some of the patients, but in no case has there been an appreciable return of muscular power. The chief causes of failure in Hughes' opinion are: 1. The long interval between the dates of injury and operation, and 2, the difficulty of obtaining perfect apposition, especially in the case of the smaller nerves. If the general result is to be failure to restore muscular function want of success must be admitted and resort must be had to tendon transplantation.

Military Antituberculosis Program.—The National Association for the Study and Prevention of Tuberculosis, in cooperation with the Surgeon General, the Y. M. C. A., and other agencies announces the completion of a program for the prevention of tuberculosis in the Army. The program includes a follow-up for every man discharged from the army on account of tuberculosis and also a thoroughgoing health education campaign among the soldiers. An obstacle to the follow-up program was Section Eleven of the Selective Service Regulations regarding the second draft, which forbids giving a record of a man's condition to anyone except certain designated officials. The officers of the National Association have placed before the War Department the importance of this work and have been influential in persuading them to open the records of rejected men to state and local boards of health throughout the country. Inasmuch as this section of the regulations does not apply to men dismissed from training camps after they have passed the draft boards, the Association has arranged with the Surgeon General and the division surgeons in camps to receive the names of all men thus dismissed. These lists are divided up by States and forwarded to State associations and State Boards of Health for follow-up work. The Medical Department of the Army has perfected its machinery for weeding out these cases. The Association is cooperating with the Government in providing sanatoria for those men who have been discharged from the service on account of tuberculosis. Such men will be cared for as near their own homes as possible in sanatoria accommodations provided by the Government.

Deaths in the American Expeditionary Force.—The list of deaths sent to the War Department by General Pershing on January 15 was the longest yet sent for any one day. Exclusive of two engineers, who lost their lives as a result of the action at Cambrai, on November 30, there were 37 soldiers in this day's list. Of these 39 deaths, 26 were due to pneumonia. The heavy death list from pneumonia is attributed to the severe winter weather in France, though intimations are not wanting that the force in France is not properly clothed.

Deaths in United States Army Camps.—The War Department reports that for the week ending January 11 there were 235 deaths among the National Guardsmen and the National Army. Of these 235 deaths 149 were caused by pneumonia. Both the hospital admissions and the non-effective rates increased in the National Army and National Guard camps, with pneumonia generally prevalent. Among

the Guardsmen there were 342 new cases of pneumonia, and in the National Army 340. The meningitis situation continued to improve in both the National Guard and the National Army. Epidemics of German measles and mumps prevailed in many of the camps. Scarlet fever increased in the National Army and decreased in the National Guard. Camp Doniphan, Okla., reported the largest number of new cases of pneumonia, 50, while Camp Wheeler reported the next largest number, 47. Camp Travis, Texas, headed the National Army camps with 94 new cases of pneumonia, against 72 the week before. Camp Pike, Ark., was second, with 41 new cases. Camp Lee, Va., reported 24 new cases against 59 for the week before. Reports of a high mortality at Camp Wadsworth, Spartanburg, have been officially denied. The statistics of the camp show that in three months the admissions to the hospital have numbered 2,470; during three months there were 233 deaths, or a mortality rate of 0.44 per cent., which the record states has been unequaled by any hospital, military or civil, in the country.

University Behind the Lines.—A report from the Canadian Headquarters in France states that a Canadian division has established a university behind the lines. Classes will be held in such places as brigade divisional schools and Y. M. C. A. huts. It has among its senate and staff men of recognized academic standing throughout the Dominion. Lectures on a wide range of subjects are provided.

New Rockefeller Hospital.—Plans have been perfected and the contracts let for converting the Billings estate on Washington Heights, New York, into a war hospital. This property, comprising fifty-seven acres of land, was purchased about a year ago by John D. Rockefeller, Jr., with the idea of eventually giving it to the city for a park. The plans for the war hospital call for the expenditure of \$500,000 for remodeling the buildings already on the property and the erection of additional buildings necessary to the completion of a hospital system.

Red Cross School for Cripples.—The American Red Cross announces the gift of \$50,000 by Jeremiah Milbank to be used in establishing a school for the reeducation of disabled soldiers and sailors. The school will be housed at 311 Madison Avenue, New York, in the building formerly occupied by the College of Physicians and Surgeons. The activities of the institute are already in operation, the staff having been engaged in study and preparation for the work during the past six months. The committee in charge of the enterprise consists of Douglas C. McMurtrie, Director, and Lieut. Col. C. H. Connor, of Washington, is Chairman; Jeremiah Milbank, Vice Chairman, and the other members are Captain Sidney Burnap, M. O. R. C., and Dr. Richard M. Pearce, of Philadelphia.

Red Cross Aid for Italy.—On the recommendation of the special Italian relief commission, the American Red Cross has appropriated \$4,771,990 for military and civilian relief in Italy for the seven months, beginning last November 1.

The Gatti-Casazza Ambulance.—The directors of the Metropolitan Opera Company have voted to present an ambulance to the Italian Government in the name of the manager, Mr. Gatti-Casazza, to commemorate the end of his first ten years of service.

MEDICAL RECORD.

CONGENITAL WORD-BLINDNESS.

It would perhaps be supposed that such a serious cerebral defect as congenital word-blindness could be easily picked out in the young children, and such cases segregated, almost at once in our schools. The histories of these patients, however, show that quite often they go to school several years, either keeping up with their classes by sheer quickness in memorizing lessons, or being considered mentally backward because they fail to learn to read. Although acquired word-blindness as an isolated condition has been known since 1877, the first paper on the congenital form appears to have been by Morgan in 1896. Since then many writers, especially Hinshelwood, have given great attention to the subject.

Whenever a child fails to learn to read after a reasonable amount of effort has been made to teach him, this condition should be suspected. It will sometimes happen that the child in question learns his letters easily, reads figures and musical notes readily, and may be highly intelligent. It must be remembered that in learning to read the child first stocks his visual memory with the letters of the alphabet, the seat of this knowledge being the left angular gyrus, while the auditory memory center, in the temporosphenoidal lobe, receives the sound of the words as spelled. Words may then be recognized by spelling them aloud or by conjuring them up in the mind, letter by letter—a slow process, of course. The next stage in reading is much more difficult of attainment, being the storing up in the visual memory of the words themselves, so that each word becomes, not a combination of letters, but a symbol, recognized at once and conveying a definite idea.

The word-blind child never reaches this stage. Assuming that the center for the visual memory of words and letters is in the angular and supra-marginal gyri of the left side of the brain in right-handed people, and *vice versa*, the more important part being in the angular gyrus, we conclude that in these children there is some abnormality of this area, due to disease, injury at birth, or faulty development. Any condition diminishing the number of the cortical cells within this area, or interfering

with the blood-supply, would lower the functional activity of the center, and hence diminish the power of retention of the visual images of words and letters which is absolutely essential for the successful accomplishment of the act of reading. Varying degrees of damage to this center are accompanied by varying degrees of defect. Cases have been reported in which the first few members of a family escaped this defect, but the rest had it. Such cases point to a defective development of this cerebral area, occurring in the early stages of the embryonic growth.

If it will be remembered then that congenital word-blindness is much more common than is generally supposed, occurs more frequently in boys than in girls, may exist alone, even in an individual who reads figures, spells, and reads music correctly and is unusually intelligent, we shall be able to pick out these cases more often.

The prognosis, too, is not so gloomy as is frequently stated. These children will not get along in the crowded school-room, where they can get only the same, or at the best a little more attention than the rest of the class. They should be educated to read in a very special manner. In most cases this can best be done by teaching the words letter by letter and thus appealing to the auditory memory, but in some of the cases the present-day method of teaching, that is, the recognition of words as a whole, will be found best. It is only, of course, when the defect is unilateral that we can expect results, so when the difficulty in learning to read is associated with a general failure of the intellectual powers it usually means that both sides are pathological and hence there is nothing to build on.

TESTING THE STATE OF THE HEPATIC FUNCTIONS.

A GENERATION ago there were but few ready resources available for obtaining an idea as to the functional capacity of the liver. The presence of bile in the liver was only a corollary of the existence of icterus. Urobilinuria was believed to point to some defect in hepatic metabolism while the presence of tyrosin crystals signified destruction of the hepatic parenchyma. Professor Gautier of Geneva, writing in the *Revue Médicale de la Suisse Romande* for Oct. 20, states that clinical evidence of a dependable sort as to functional incapacity of the liver, especially in its milder aspects, is still very defective. There are many resources available for exploring the hepatic functions, and this fact alone implies that none is conclusive. Some old ones are still employed, although their value is questionable; others are recent and have hardly made good. During the past few years the entire subject has been repeatedly written up.

The alimentary glycosuria test is very old, having been suggested as far back as 1875, although it did not find its way into text books until many years

later. For a considerable time, of late years, it has been highly regarded, and only recently have doubts been thrown upon its value. Recent work in Switzerland has led to a conclusion already formulated in 1902 by Ducamp that it is indecisive in its results. We can, however, admit that something is wrong with a liver which cannot use up 150 grams daily of glucose. In regard to bile in the urine, when both coloring matters and salts are present the significance, so far as hepatic function goes, is *nil*. If, however, either product is found alone—in other words, if biliary dissociation is present—one may suspect the existence of a non-obstructive icterus or a cirrhosis of the liver. In cirrhosis we may find bile salts in the urine with urobilinuria, but no bile pigment. The author has found this dissociation in a considerable number of cases of infectious icterus, cirrhosis, and cholangitis. The subject of urobilinuria as related to hepatic insufficiency is no longer a simple matter because urobilin and its congener urobilogen are known to occur under most varied conditions. In connection with other positive finds, however, urobilinuria may possess value.

The unsatisfactory evidence afforded by the urine has inspired studies of the blood to determine the presence of bile salts and pigments, but this has been found impracticable. Of much more value is the research for the particles known as hemoconia, of ultramicroscopic character, the presence of which in the blood may point to structural lesions of the liver.

The author mentions research of the stools, study of the nitrogen partition of the urine, glycuronuria, and other fields of activity in connection with the diagnosis of hepatic insufficiency, and finds a source of error common to all methods thus far used. Not one of them bears exclusively on the functions of the liver, for to a greater or lesser extent the organism at large is involved in the mechanism. Herein lies the great difference between theory and practice.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE U. S. PUBLIC HEALTH SERVICE.

THE annual report to the Secretary of the Treasury of the Surgeon General of the Public Health Service for the fiscal year ending June 30, 1917, has been published recently. The field work of the organization has been conducted through seven divisions, as follows: Scientific Research, Foreign and Insular Quarantine and Immigration, Domestic Quarantine, Sanitary Reports and Statistics, Marine Hospitals and Relief, Personnel and Accounts, and Miscellaneous.

Scientific research for the last three months of the fiscal year was mainly concerned with health problems arising from the entrance of this country into the war. Now that America is engaged in raising a large army and placing it in camps in different parts of the country, the problem of stamping

out or of controlling communicable diseases is of greater importance than ever before. Typhoid fever, formerly the greatest scourge of military camps, is, on account of the efficacy of antityphoid inoculation and of other means of prevention, well under control, but trachoma, which has been a grave menace to the efficiency of the armies of Europe, has to be dealt with. The report points out that careful inspection of recruits by the military authorities and treatment of those found to have the disease must be supplemented by efforts of health officials to keep the disease from being transmitted from civil to military populations at the different cantonments.

Interesting studies with regard to pellagra were made during the year under the direction of Surgeon Joseph Goldberger. The investigations as to the intimate association of pellagra with diet have had most illuminating results. They have shown that the disease can be prevented by appropriate diet and can even be cured by dietetic treatment. A great deal of useful work has been done in relation to trachoma, and as mentioned before, it is incumbent on health authorities throughout the country that the disease should be kept away from the military camps.

Carl Voegtlin has been continuing his studies on the physiological significance of vitamins in nutrition. During the year it has been determined that exposure of meat to a temperature of 120° C. for three hours does not destroy the antineuritic vitamin contained in the food. This observation would seem to indicate that the canning of meat is a procedure which does not necessarily destroy the antineuritic vitamin. Another interesting investigation undertaken to determine the toxicity of commercial preparations of emetine resulted in demonstrating that the various preparations do not differ appreciably in toxicity. Typhus fever, which was rife along the Mexican border, has been studied carefully by the service. It seems to have been established completely that lice are chiefly if not wholly responsible for its spread and consequently sole reliance in the way of prevention has been placed on rendering incoming travelers free from lice and excluding those obviously ill.

With respect to the needs of the Service, it is pointed out in the report, that one of the most important is that of making national quarantine complete. Another somewhat pressing need is that of an increase in the number of commissioned officers in the Service. The bill to establish a Sanitary Reserve Corps of the Public Health Service was passed by the Senate in June, 1917. In the House of Representatives, however, a committee to which the joint resolution was referred, reported a substitute measure. An organization such as proposed in these two measures, consisting of trained sanitarians and health officers

would be of the greatest assistance in the case of epidemics and of other public health emergencies. The passage of a bill authorizing the establishment of an organization of this nature, is therefore earnestly recommended to the consideration of the National Legislature. The officials of the Public Health Service have always done such efficient work in the prevention of disease and in caring for the public health that Congress must see to it that no obstacles are put in their way, especially at this time of peril to the country.

THE CURE OF LEPROSY.

AMELIORATION, or even arrest of certain cases of leprosy, under intensive treatment, is often enough reported, but authentic instances of permanent cure extending over many years are rare. Failure to find the bacilli cannot be regarded as evidence of cure, and serodiagnosis does not appear to be trustworthy. The provocative use of iodide of potassium may possess decisive value. Dr. Cleves Vargas, now of Bogotá, but formerly head of a leprosarium at Agua de Dios, believes that he has cured several lepers, and reports one case in detail in a man of 55 who had once cohabited with a female leper (*Revista de Medicina y Cirugia de la Habana*, November 25). The patient insisted that the first lesion noted was a nodule in the balanopreputial fold. Upon his entrance into the institution he presented a pronounced case of mixed leprosy and Hansen's bacillus was found in the lymph. He was at once placed on an abundant and nutritious diet, but was given no meat or fats and no alcohol, save a little beer. He was made to exercise out of doors until he sweated profusely, and was also given hot baths and decoctions containing eucalyptus and similar drugs. Chaulmoogra oil he received internally and by inunction. After six months, improvement was noted, and at the end of a year he was apparently cured. The integument was quite normal, sensory disturbances had disappeared, and bacilli could not be found in the lymph or elsewhere. The responsibility for discharging him from the institution was great, and four physicians had to concur in the diagnosis of recovery. For three days he took large provocative doses of iodide of potassium, but bacilli were not to be found in the secretions, and no suspicious lesions appeared on the skin or mucosæ. The patient was therefore discharged.

ACUTE EPINEPHRITIS IN MALARIAL FEVER.

FRENCH authors have called attention to a marked suprarenal syndrome in malarial fever which was perhaps regarded as functional, and analogous to similar behavior in other acute infections. A fatal case reported in the *Brazil-Medico* for October 13, by Fraga, appears to show that this organ may be acutely inflamed in malaria. The case was one of three in which, clinically, the suprarenal syndrome was present. In the fatal case the comatose patient showed muscular resolution, eyes open and staring, pupils dilated, nose cold and moist, mouth half open, lips retracted, breathing stertorous, surface cold, and covered with clammy sweat, pulse filiform, apex beat imperceptible, heart sounds extinguished, axil-

lary temperature 94.1° F. The spleen was greatly enlarged, and the lower border of the liver a finger's breadth below the costal arch. The patient was in this condition when first seen, and tropical malaria was at once suspected. A blood examination showed the presence of the *Hematozoon falciparum*. The autopsy, made 12 hours after death, showed both suprarenals congested and enlarged; each weighed 10 grams, with greatest diameter 7 cm. The hematozoon was seen in the capillaries of the cortex, one to a field. The histological alterations were those of an inflammatory process. Dr. Fragas' paper was read before the Medical Society of the Bahia Hospital, and he was felicitated by his colleagues for his priority in reporting a case of this type (clinical diagnosis with full autopsy confirmation).

News of the Week.

Meeting of the General Medical Board of the Council on National Defense.—This body held its regular meeting in Washington, D. C., on January 13, 1918, at which time resolutions were presented and adopted on the deaths of Dr. Theodore Janeway and Dr. Everett J. McKnight and sanitary reports were received from the various committees of the General Medical Board. The report of Admiral Braisted expressed gratification over the fact that his request for a meningitis segregation camp in Florida had been granted. It is hoped to isolate in this camp all meningitis carriers and to care for them until they are again safe. Surgeon General Gorgas, in his report, dwelt upon the present state of the health of the army. He cautioned against the possible mistake of referring the pneumonia epidemics solely to the cold weather, and was inclined to the opinion that this was only an indirect cause, the real cause being the closer housing of the men in cold weather. Dr. S. McC. Hamill reported that the committee on child welfare was centering its attention on a program covering the welfare of the mother, as well as all forms of child welfare work. He presented resolutions aiming to secure the closer cooperation of the medical schools of the country along lines of child-welfare work. Dr. Francis D. Patterson presented a program for the reconstruction, rehabilitation, and reeducation of disabled men, covering medical and surgical treatment, vocational training, the securing of employment, and the maintenance of medical supervision. He also emphasized the necessity of educating employers up to the point of recognizing the need of cooperation on their part in the proper utilization of the reconstructed soldier. Dr. Joseph Schereschewsky outlined the aims of industrial surgeons to provide against unnecessary human waste in industry and society during the war by the avoidance of preventable deaths and disabilities from accident and diseases and improving the sanitary conditions under which people in industry work and live. Dr. Edward P. Davis of Philadelphia submitted a report advocating the establishment of an auxiliary medical service corps which would utilize the services of men who, either by age or physical disability, are disqualified from receiving a commission, but who, nevertheless, are potentially of service to the country. For the Com-

mittee on General Surgery, Dr. J. Bentley Squier of New York reviewed the progress that was being made in classifying the various surgeons of the country with reference to their professional qualifications and personality. He stated that up to the present time 21,000 applicants for the Medical Reserve Corps had been coded in such fashion that at a moment's notice the medical authorities of the War Department may secure almost any desired type of information regarding any individual in the service or waiting for commission. Dr. Rosalie Slaughter Morton, reporting for the women physicians, stated that this committee had on its registration the names of 1,796 women physicians, or approximately one-third of all the women physicians registered in the United States. It is hoped that these women may at least help meet the need of internes, laboratory workers, radiographers, and anesthetists. Dr. Victor C. Vaughan submitted the report for the Committee on Cooperation which emphasized the necessity for close cooperation between civilian authorities and military authorities in the regulation of health matters concerning both of these branches. In the State of Michigan, where very close cooperation existed, infectious diseases occurring in the civil population are immediately reported to the military authorities in the nearby cantonment by telephone or telegraph. This enables the military authorities to institute efficient quarantine. Such cooperation should be established between all civilian and military health authorities throughout the country. The General Medical Board adopted resolutions endorsing the plan of daylight saving and will lend its influence in securing the passage of a law directed toward this end.

Plague in China.—A pneumonia type of plague is prevalent in Fengchen, China, and in other parts of the Shansi Province. Appeals for help are being sent broadcast by the American doctors who recently went into the province to investigate the plague conditions.

Daylight Saving Bill.—The Committee on Interstate Commerce of the House of Representatives of New York State has under consideration a bill which provides that the clock be advanced one hour in April and moved back in September. The Health Department expresses the opinion that health authorities everywhere should welcome this movement as distinctly in the interests of public health since it will promote outdoor life and all the benefits that go with it.

Course in the Treatment of Infected Wounds.—The Long Island College Hospital announces a practical course in the Treatment of Infected Wounds for medical officers of the Army and Navy. The course consists of ten daily sessions, except Saturdays, from 9 to 12 o'clock. The classes are limited to six members. A new class will be started the first and third Mondays of each month.

New York State Medical Society Remits No Dues.—The Kings County Medical Society, as well as a number of county medical societies throughout the State, has remitted the dues of its members in the service for the period of the war. Under the By-Laws of the State Medical Society three dollars of the dues paid by each member of a county society go to the State Society. The State Society now

announces that it will not remit any dues, but will expect the usual tax of three dollars for each member. This means that the dues of those in the service will have to be paid from the treasuries of the county societies or by an additional tax on the doctors not in the service. As the Kings County Medical Society has about 110 of its members in the Federal service it is disposed to be sharply critical of the attitude of the State Society.

Civil Service Positions Open.—The Civil Service Commission of New York State announces the following examinations: *Medical Adviser*, Division of State Insurance Fund, State Industrial Commission salary \$2,500. *Resident Physician*, State Agricultural and Industrial School, Monroe County; salary \$1,500 to \$2,000, with maintenance for the physician and his family. *Assistant Physician*, Regular or Homeopathic, for State hospitals and other positions of similar nature in various State and county institutions. The salary is \$1200 with \$100 increase each year for four years. For further information and application form address the State Civil Service Commission, Albany, before February 11.

Dr. Haven Emerson, ex-Health Commissioner of New York City, has been commissioned major in the Medical Reserve Corps, and has been assigned to duty in the Surgeon-General's office.

Dr. James Barrett has been elected city physician of South Portland, Me., to succeed Captain L. S. Lombard, now in the service.

Dr. James B. Atwater has been elected to the Board of Health of Springfield, Mass., to fill the vacancy caused by the resignation of Dr. Frederick D. Davis.

Dr. May S. Miles of Greensboro, N. C., has been elected president of the Guilford County Medical Society for the ensuing year.

Dr. George Gray Ward, Jr., has been appointed Chief Surgeon and Surgical Director of the Woman's Hospital to succeed Dr. Clement Cleveland resigned.

Dr. William J. Mayo of Rochester, Minn., was awarded a gold medal by the National Institute of Social Sciences at its annual banquet in New York City, on the evening of January 18. The medal was bestowed in recognition of Dr. Mayo's humanitarian work. At the same time medals for services in their special fields of work were presented to Dr. Thomas W. Salmon, Professor C.-E. A. Winslow, Professor Irving Fisher, and Dr. John A. Kingsbury, ex-Commissioner of Charities of New York City.

Harvey Society Lecture.—Prof. John Gordon Wilson of Chicago will deliver the next Harvey Society lecture at the New York Academy of Medicine on the evening of February 9, at 8.30 o'clock. His subject is "The Effect of High Explosives on the Ear."

The Associated Physicians of Long Island will hold their twentieth annual meeting at the Long Island College Hospital, corner of Henry and Amity streets, on January 26. Medical and Surgical Clinics will be held from 10 A. M. until 1 P. M. The annual business meetings will be held at 2.30 and will be followed by the scientific session.

Crime Decreases in New York State.—The annual report of the Secretary of State transmitted

to the Legislature, on January 15, shows that there were 6,980 persons confined in the penal institutions of New York State on January 1, 1916; 6,517 on January 1, 1917, and 5,916 on January 1 of this year. There were 1,423 fewer convictions in the courts of Special Sessions during 1917 than during the previous year. Of 67,969 persons convicted 64,243 were males. Of 7,930 persons convicted of graver crimes 5,084 were natives of the United States, 2,881 were married, 7,440 could read and write, and 7,274 professed to be of temperate habits. Only 2,902 had been convicted of previous crime. The trades and pursuits furnishing the largest number of criminals, respectively, were laborers, clerks, chauffeurs, salesmen, farmers, waiters and carpenters.

Calls Heroin an Unnecessary Drug.—The Whitney Legislative Committee which has been investigating the drug evil has resumed its hearings. Dr. Charles F. Stokes, formerly physician in charge of the New York City Colony Farm at Warwick, N. Y., in his testimony before the committee recommended the establishment of another farm colony especially for the treatment of drug addicts. He also expressed the belief that the medical profession could do without heroin and that the manufacture of this drug should be stopped.

Street Accidents in December.—The Bureau of Statistics of the Police Department of New York City reports a decrease in the number of street accidents in December, 1917, as compared with December, 1916, the figures being 1,576 for December, 1917, and 1,800 for December, 1916. The report calls attention to the fact that the heavy snowfall compelled pedestrians to keep to the crossings and believes this accounts for the reduction in the number of street accidents. The total number of persons killed or injured decreased from 1,950 in December, 1916, to 1,701, in 1917. It was observed that during this month as at former times the largest number of street accidents, one-third of the entire number, occurred during the three hours from 5 to 8 P. M.

Prohibition Bill Before New York State.—The Anti-Saloon League has introduced a bill before the Legislature of New York which would make New York State bone dry from October 1, 1918, for the period of the war and for a period of demobilization of one year thereafter. The bill would permit the manufacture and sale of alcoholic liquors for medicinal, mechanical, scientific, or sacramental purposes where such manufacture and sale are not now excluded by the vote of the people.

Clinic for the After-care of Infantile Paralysis.—The State Department of Health is conducting a third series of clinics for the after-care of infantile paralysis at various places throughout the State. The clinical staff of the traveling unit consists of Dr. Le Roy W. Hubbard and four nurses experienced in this work. Since the Department of Health undertook this work last year 160 clinics have been held in various centers of population at which 3,800 individual examinations have been made. To date 76 operations have been performed. Braces or some form of apparatus have been furnished to 527 cripples. All of the cases seen at the clinics have been visited repeatedly by the State supervising nurses.

Smallpox at the Cattaraugus Indian Reservation.—Quarantine at the Cattaraugus Indian Reservation has been raised, only a few cases still being in isolation. During the recent epidemic there have been in all 96 cases of smallpox isolated.

The Wetumka Medical Society, at its regular meeting in Wetumka, Okla., on December 28, elected the following officers for the ensuing year: *President*, Dr. J. A. Hemphill; *Vice-President*, Dr. O. S. Burrow; *Secretary-Treasurer*, Dr. C. A. Hicks.

St. Louis Hospitals Share Fund.—The Hospital Saturday and Sunday Association of St. Louis has just divided a fund of \$43,951, the result of its annual campaign among fifteen hospitals of that city. This year's collection exceeds that of last year by \$7,275.

An Appeal to the President.—At the annual meeting of the National Institute of Social Sciences, held at the Hotel Astor on Friday, January 18, the following resolution was adopted: "Resolved, that the President of the United States be urged to institute adequate measures for the conservation of the health and the promotion of the physical efficiency of the nation during the period of the war."

Obituary Notes.—Dr. FREDERICK MORSE WILSON of Bridgeport, Conn., died at Colon, Panama, on December 17, aged 66 years. He was graduated from Tuft's College Medical Department in 1875.

Dr. WILLIAM HENRY LATHROP of Lowell, Mass., died after a brief illness at his home in that city at the age of 77 years. He was graduated from the University of Pennsylvania, in 1865, and served as an assistant surgeon with the Army of the Potomac during the Civil War. Dr. Lathrop formerly resided in Detroit, where for some years he was editor of the *Detroit Review of Medicine* and physician to the Detroit Retreat for the Insane. He located in Lowell, Mass., in 1883, where he continued to practise medicine up to the time of his death.

Dr. GLENN MITCHELL LITSINGER, a graduate of the College of Physicians and Surgeons, Baltimore, in 1898, and a member of the faculty of the University of Maryland, died of septicemia, at his home in Baltimore, on December 26, aged 45 years.

Dr. JOHN HARRIGAN, a Brooklyn obstetrician, died of heart disease at his home, on December 30. He was a graduate of the Long Island College Hospital, in 1874. He served in the medical department of the Union Army during the Civil War and was a member of the staff of St. Mary's Hospital for more than twenty-five years.

Dr. THEODORE G. FINLEY of Los Angeles, Cal., died in the Sisters' Hospital in that city, on December 17, aged 42 years. He was graduated from the College of Medicine of the University of California, in 1908. He was formerly assistant superintendent of the Los Angeles County Hospital and at the time of his death one of the surgeons of the Los Angeles Gas and Electric Corporation.

Dr. ROBERT CHILTON ATKINSON died at his home in St. Louis, Mo., on December 31, aged 76 years. He was a graduate of the Medical Department of Tulane University, in 1867. Dr. Atkinson was appointed a member of the Board of Health of St. Louis in 1884 and served for a term of four years, when he was appointed secretary of the State Board

of Health, serving in that capacity for two years. He was a member of the Board of Hygiene of the public schools and medical director of St. Ann's Foundling Asylum. For eighteen years he occupied the chair of children's diseases in the Marion Sims Medical College, retaining the same position after the college had been absorbed by the University of St. Louis.

Dr. WILLIAM HENRY SANDERS of Montgomery, Ala., died at his home in that city after an illness of more than two years, on January 2, aged 79 years. He was graduated from Jefferson Medical College, Philadelphia, in 1861, and served through the Civil War as surgeon in the Confederate Army. Dr. Sanders was State Health Officer of Alabama for 20 years, retiring about a year ago because of ill health.

Dr. MARY L. FARNUM, formerly of Woonsocket, R. I., died at the Good Samaritan Hospital in Portland, Ore., on January 2, aged 54 years. She studied medicine at the Woman's Medical College, Philadelphia, and completed her medical education in Germany. Since removing to Portland, ten years ago, she has devoted herself to philanthropic work along medical lines.

Dr. JAMES O'DONNELL, a graduate of Bellevue Hospital Medical College, in 1892, and for twenty-seven years a practising physician of Paterson, N. J., died in St. Joseph's Hospital in that city after a brief illness, on January 7, at the age of 50 years. He was for six years president of the staff of St. Joseph's Hospital.

Obituary.

WILLIAM HANNA THOMSON, M.D., LL.D.

NEW YORK

DR. WILLIAM HANNA THOMSON, for over fifty years a conspicuous figure in the medical life of New York, died at his home in this city on January 18, in his eighty-fifth year. He was the son of a missionary, and was born in Beirut, Syria, in 1833. At the age of nine years he was sent to America to be educated, and returned to Syria at the end of eight years with the degree of A.B., obtained at Wabash College in 1850. Remaining in Syria several years, he came back to this country to complete his medical education, which he had begun in Beirut, and was graduated from the Albany Medical College in 1859. After graduation he removed to New York City, and was for a couple of years assistant physician at the quarantine station at this port. During the Civil War he served as medical inspector in the Navy. In 1868 he was appointed physician to the Charity (now City) Hospital, and was also for many years attending physician to Roosevelt Hospital. For some time he was professor of medicine at the New York University Medical College. He was a member of the Medical Societies of the County and State of New York, of the Association of American Physicians, and of the New York Neurological Society, and a fellow of the American Academy of Medicine and of the New York Academy of Medicine. Dr. Thomson contributed largely to medical literature and also wrote along other lines, being the author of two widely known books, "Brains and Personality" and "Life, Death and Immortality."

Correspondence.

PINK PALMS IN INFLUENZAL PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—A number of clinicians have at times expressed the belief that the palms of the hands in patients who are ill with typhoid fever often take on a peculiar chrome yellow appearance. This is largely dependent in its development upon how thick the skin of the palms of the hands has become through toil. It is not constant, but, nevertheless, in some patients the chrome yellow color is certainly noticeable. I have not seen any record of a pink and mottled erythematous, or dusky erythematous, color of the palms of the hands, noticeable from the base of the thumb to the wrist and from the base of the little finger to the wrist in influenzal pneumonia, but clinically I have observed this quite frequently. The appearance is somewhat similar to the discoloration caused by the contact of an unduly hot hot-water bag applied to the abdomen. I have noted it more frequently in severe cases than in moderate ones and I have come to regard it as indicative of a particularly severe infection. As one would expect, this symptom is best seen in those whose hands are not hardened by manual labor.

CORNER SPRUCE AND EIGHTEENTH STREETS,
PHILADELPHIA.

THE USE OF A FACE MASK IN COMMUNICABLE DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the issue of the MEDICAL RECORD for August 12, 1916, a letter of mine is published which contains the following statements: "*I therefore suggest that the faces of the patients, as well as that of the attendants, should be protected by a fine mesh net.*" While this will not give a protection of 100 per cent., it may assist to some degree in checking the disease. The employment of this means will bring no hardship to the patients or to the attendants." This suggestion occurred to me after observing for some time the somewhat careless intercourse of physicians, nurses, and the little patients of pyliomyelitis in a ward of a large hospital under the care of the Board of Health. The Health Commissioner to whom I made the above suggestion informed me that "the advisory committee considered that no benefit to the public or to the individual can be expected from following the procedure proposed." That was the last of it. I closed my letter by saying: "In looking over the names of the advisory committee it occurred to me that it would be humane and in accordance with sane public health rules, if some of the members (of the advisory committee) who rush from places of infection to their private patients would accept my proposal."

I was reminded of my letter by reading in the issue of the *Journal of the A. M. A.* for January 12 an article by Dr. George H. Weaver of Chicago (from the Memorial Institute for Infectious Dis-

eases), entitled "The Value of the Face Mask and Other Measures." In the Durand Hospital, in which patients with a variety of contagious diseases are housed they have tested the protective value of face masks worn by patients, nurses, and physicians. The masks they have used "consist of a double thickness of gauze, so shaped as to fit closely over the face from the chin well over the nose, and held in place by two tapes tied behind the head." Weaver states that "coincident with the use of masks there has been an absence of diphtheria or bacillus carriers among the physicians, and only a limited amount of throat infections."

"We feel that great protective usefulness resides in this mechanical measure, and think that it might be used to advantage also by persons caring for pneumonia patients. . . . The mask not only protects the healthy person from infection and from becoming a carrier, but also prevents a carrier from spreading infection to others. Masks can be used to good advantage in households in which are patients of diphtheria, pneumonia, scarlet fever, epidemic meningitis, or other diseases spread by nasopharyngeal discharges."

The standing of Dr. Weaver needs no comment from my side, except, perhaps, of saying that it is not lower than the standing of the members of the above mentioned advisory committee of the New York Board of Health. Weaver's statement merits consideration, *especially at present, with reference to pneumonia patients.*

There is a moral to this tale. A commissioner of health should permit himself to be openminded, and take under consideration a common-sense advice even when the advisory committee considers it as being of no benefit to the public. The appointments to membership in the advisory committee are, as we all know, not always dictated merely by the specific merits of the appointees.

ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

REGISTRATION OF PATIENTS WITH INCURABLE DISEASES NO LONGER DEMANDED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a letter to the MEDICAL RECORD, published on November 24, 1917, I called attention to the official blanks issued by the New York State Department of Health, which contained a demand for the registration, in common with that of drug addicts, of patients suffering from incurable disease to whom morphine had to be administered. This I contended was an illegal interpretation of the law, which should be resisted at all hazards by the physicians as a breach of professional privilege.

Later on, the appearance in this city of the attorney of the State Board of Health, Mr. Joseph A. Warren, as an advocate of an amendment to the drug laws creating a specially licensed class of physicians to prescribe for drug addicts, gave an opportunity of calling his attention through the public press to this illegal requirement of his board, as a matter more worthy of his attention than the creation of a new specially privileged class of medical licensees by the State.

According to a letter received from the State Board of Health by a physician of this city, these

blanks are no longer issued by this department. In this letter the physician was advised to report his cases on his own letter heads, which, of course, contained no such requirement as the one objected to.

Inasmuch as this abrogation of the State Board's requirement in this instance has not been publicly announced so far as I am aware, I think its promulgation is worthy of publication in your journal to show what may be accomplished by a proper defense of the rights of physicians, even when advanced by individual members of the profession in the absence of concerted action by the organized medical bodies.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

RED CROSS WORKING IN FRANCE—AN AMERICAN HOME FOR SOLDIERS—THE NEW BREAD REGULATIONS.

PARIS, December 10, 1917.

THE American Red Cross recently opened an Exposition of Gifts for its work at 136 Avenue des Champs Elysées for the duration of one week. Each day there will be a lecture by the heads of various departments explaining and illustrating their particular work. Dr. William Palmer Lucas, who is the director of the service for children, spoke on what the American Red Cross is trying to do for the children of the war. Mr. James R. Barbour, general secretary of the Red Cross, and M. Firmin Roz each delivered a short address, explaining briefly what the society had accomplished and what its duties consisted of in centralizing war relief work under a national organization.

Dr. Lucas showed on a map of France eight different centers where the work for the children had been organized, speaking particularly of the work for the refugee children at Toul and for the rapatriés at Evian and other bases in that vicinity. He said that the medical service had been greatly developed at Toul, where 400 children who had been brought from the districts in the North, where the gases had played such a prominent part in the German work of destruction, were being cared for in the hospitals. Small hospitals had been established in other villages near, making three medical centers, and he spoke interestingly of the traveling dispensaries as relieving suffering among the children in an efficient manner. Dr. Lucas also spoke of the work at Chalons in charge of Dr. Davis and the cooperation in that vicinity with the American Fund for the French Wounded. In speaking of the efforts made at Evian he said that though this work was still young it had already proved of the greatest good and was by far the most heartrending of all the work for children. A hospital of 100 beds had been established at Evian and the Casino had been turned into a home for receiving all of the rapatriés before they were sorted and distributed to the hospitals and homes. Particular attention was being paid to preventing disease from spreading, especially in the case of the tuberculosis patients, which branch of the Red Cross was growing to be one of the most important.

Dr. Lucas also explained the work at Lyons, where 2,000 children are being cared for, and laid stress on the fact that a social service to visit the French homes and cooperate with the mothers would be one of the future aims of the Red Cross in making a study of how to reduce infant mortality. He also spoke of the recreation work for the children that was being developed and the necessity of cooperating with the various French societies.

The formal opening of the Home Service for American Soldiers Abroad took place yesterday in the way of a reception at its rooms in the Hotel Liverpool, rue de Castiglione. The Service is well named, as it serves for a cozy home for the boys who long for one, and Mrs. Weeks and her friends seem to know what the boys like best. Hospitality is given in abundance, so there is no doubt as to the success of the undertaking. The Service was organized by Mrs. Weeks in memory of her son, Kenneth Weeks, and his comrades who have been victims of the war—Kiffin Rockwell, Victor Chapman, James McConnell. The rooms are comfortable, and offer a welcome to all American soldiers for tea, and the members have already expressed their gratitude for such a service, though it has been organized only two weeks.

The French Minister of Agriculture and Supplies has drawn up the decree relating to bread consumption, the requisition of cereals, and the making of flour, and this decree has been signed. The principal articles are as follows: The bread rations to be allowed to each consumer, according to his or her social condition, are as follows: (1) Persons engaged in hard manual labor: Males of more than 16 years of age, 600 gr.; women of more than 16 years of age, 500 gr. (2) Persons engaged in light trades: Males of more than 16 years of age, 400 gr.; women of more than 16 years of age, 300 gr. (3) All consumers not included in the above categories (maximum per head and per day): Males of more than 16 years of age, 200 gr.; women, 200 gr.; children of both sexes, 200 gr.

In communes or agglomerations of communes of more than 20,000 inhabitants the prefects are empowered to issue individual bread cards after consultation with the municipal councils. These cards are not transferable. At the same time as the card the communal office will distribute to consumers one or more books of tickets containing as many tickets for 100 grams as are allowed in the monthly bread ration. These books will be available only for the month for which they are issued.

When the holder of a bread card is away from his habitual place of residence at the end of the month, he can renew his card at the mairie of the commune in which he happens to be, on condition that bread cards be in use in that commune. The mayor will deliver a provisional card in exchange for the old one and return the latter to the mairie in the holder's place of residence.

Soldiers on short or extended leave receive an individual card corresponding to the amount of the highest ration during the said leave, and the card is delivered by the mairie at the place of residence indicated on the soldier's leave papers.

Persons who make a sojourn in a commune where the bread card is in force will, upon request, be furnished by the communal bread office with a "carnet" comprising a number of tickets corresponding to the visitors' consumption during their sojourn or until the end of the current month. In the event of the holders remaining for a long period the card is renewed. When the holders leave the commune the cards and carnets are to be handed in at the mairie, together with those not made use of.

Any cards found to have been lent or sold to another person will be confiscated. It is also forbidden to scratch or otherwise disfigure them. In principle, no card lost or destroyed will be replaced, but all such cases should be reported to the communal office.

The bakers and other vendors of bread or equivalent products will be furnished with flour in proportion to the quantities sold by them represented by the tickets. Those who disobey the regulations will have their supply stopped during a certain number of days, independently of any legal proceedings that may be taken. In hotels, restaurants, and other establishments where meals are served, it is forbidden to serve per meal and per consumer: (1) More than 100 grams of bread if the price of the meal is more than 4 fr.; (2) more than 200 grams of bread if the price of the meal does not exceed that sum.

2. The After-Care of the War Cripple. — E. A. McCarthy shows that in the last three years' war the experience of our Allies has brought out the fact that the wounded soldier must be considered from a different aspect than ever before. Instead of being pensioned and allowed to shift for himself he must be made over, repaired, and brought up to a period of service. He points out what the condition of Great Britain would be today, with 600,000 crippled soldiers for whom no special preparation had been made at the beginning of the war, had she not inaugurated those marvelous curative workshops for the rehabilitation of her disabled soldiers by the aid of orthopedic surgery. He mentions Col. Sir Robert Jones of Liverpool as the leader in this curative measure. Thus indolent and often discontented patients are converted into happy men who soon begin to feel that they are becoming useful members of society and not mere derelicts. These men are given employment with the tools they understand or an occupation suitable to their disability. According to Major E. G. Brackett, director of orthopedic surgery in the Medical Department of the United States Army in this country, our Government intends to adopt the system now in vogue in England, with a few changes. The Government will establish in France about 35,000 orthopedic beds, divided into units or hospitals of about 2500 beds. In this country also there will be constructed several reconstruction or rehabilitation hospitals, which will be mainly orthopedic in their nature, but will include other specialties as well as general medicine and general surgery. The purpose of the latter hospitals on this side of the water will be to take care of those

cases which can be transported without danger to the patients who need further surgical treatment and training along industrial lines for their future service in life. These men will be those who will be unfit for further military service on account of their disabilities. These American soldiers, until entirely cured and educated or trained along industrial lines, will be kept under army discipline and will not be discharged from the army until they are ready to perform usefully such service in civil life as their reconstructed crippled condition will permit. McCarthy points out what a wise decision this is on the part of the United States Government. This condition is met with so much in civil life, where industrial accidents disable a man, but there is no law to compel him to take up any other industrial work suited to his crippled condition. McCarthy, in discussing this new move on the part of the Government with reference to the establishment of reconstruction hospitals, calls attention to the fact that this is a very serious piece of work, since there are already 30,000 or over finely equipped hospitals in this country. Is it wise to deplete these already existing institutions of some of their staffs, or, instead of the reconstruction hospitals, should the general hospitals, as at present constituted, be expanded to carry on the work intended by the Government in these reconstruction hospitals? Since the number of doctors in this country, as compared to the population, is not very large, should not conservation be practised here just as well as in other departments of life? The American Hospital Association appears to be opposed to this new plan of the Government, because the hospitals realize their duty is to care for the civil population, and with depleted staffs the problem becomes one difficult of solution. The question also arises whether the civil hospitals, caring, as they do today for the many industrial cases, may not profit to a great extent in knowledge and education by taking care of the war cripple, and thereby become a greater benefit to the civil community in the future after the scars of this great world conflict have healed. The soldier has made a great sacrifice for his country; it is our duty to see to it that he gets the best possible service that can be had on his return from the front. The Government, in establishing these new hospitals, has this in view, but the scarcity of doctors and the care of the community itself are to be considered.

1. **Instruction and Supervision of Expectant Mothers in New York City.**—Jacob Sobel, Chief of the Division of Baby Welfare, Department of Health, New York, considers that the problem that faces New York with reference to this condition of expectant mothers and loss of infant life is in part as follows: (1) Forty-one per cent. of all deaths under one year of age are due to congenital diseases. (2) Approximately 37 per cent. of all deaths under one year of age occur during the first month of life; of this percentage at least 27 per cent. take place during the first ten days of life. (3) About 75 to 80 per cent. during the first month of life and approximately 90 per cent. of all deaths during the first ten days of life are due to congenital diseases. (4) During the thirty-year period from 1884 to 1914 the death rates from diarrheal, respiratory, and contagious diseases have been markedly reduced—approximately 75 per cent., 53 per cent., and 88 per cent. respectively—while the death rate from congenital diseases has been reduced only 1.5 per cent. In fact, during the past five years, the infant death rate from congenital diseases has remained practically stationary. (5) The death rate during the first month of life has remained practically unchanged for many years, while the total infant mortality rate and the rate from the second to the twelfth months of life have progressively declined.

(6) Congenital diseases take the first place in the list of "baby killing" diseases, with respiratory diseases second, and diarrheal diseases third. (7) The majority of deaths due to congenital diseases are dependent upon the health and environment of the mother before the birth of the child. (8) The number of maternal deaths incident to child bearing, while showing a reduction per 10,000 women from fifteen to forty-four years of age and per 1000 labors, is still too high for an enlightened community. (9) The death rate from conditions associated with pregnancy, other than puerperal sepsis, has declined, per 10,000 women of child bearing age, from 3.79 in 1898 to 2.9 in 1916. The puerperal sepsis death rate per 10,000 women of child bearing age during the same period has decreased from 2.58 in 1898 to 1.02 in 1916. There has also been a decrease in the puerperal sepsis death rate, based upon 1000 labors, which include stillbirths and living births, from 1.97 in 1908 to 1.55 in 1916. From other conditions associated with pregnancy per 1,000 labors, the rate has declined from 5.26 in 1908 to 4.58 in 1916. (10) That more women between fifteen and forty-four years of age died in the United States from conditions incident to maternity than from any other cause except tuberculosis, is the statement of the Children's Bureau at Washington. Sobel gives a complete outline of the work done by his department and also the Bureau of Child Hygiene of the Department of Health in furthering prophylactic and preventive measures in this direction, especially among the poor of New York. He states definitely that the mothers supervised comprise for the most part poor mothers of foreign extraction and of various races, mainly German, Russian, Austrian, Irish, Italian, Negro, and Polish. Thirteen per cent. were Americans and 87 per cent. of other races, divided as follows: Italian, 58 per cent.; Austrian, 11 per cent.; Russian, 10 per cent.; Irish, 4 per cent.; Negro, 2 per cent.; Polish, 1 per cent.; German, 1 per cent. There were few people of moderate means among this number. This should not, however, convey the impression that this class does not need supervision during the period of pregnancy. The mothers of moderate means, as well as the rich, require quite as much attention, perhaps even more, than do the poor. In point of fact, an analysis of the deaths of infants, by small sanitary districts or census tracts, has shown that the infant mortality rate from congenital diseases is greater among the rich than among the poor.

9. The Distribution of Meningococci in the Upper Respiratory Tract of Carriers. R. D. Herrold.

5. **The Value of the Face Mask and Other Measures in Prevention of Diphtheria, Meningitis, Pneumonia, etc.**—George H. Weaver outlines the prophylactic measures employed in the Durand Hospital, Chicago (a hospital for contagious diseases), including the use of the Schick test for diphtheria by which, he further states, active diphtheria practically has been eliminated from the nursing staff. Carriers, however, of diphtheria bacilli continued to be detected by weekly throat cultures. From Nov. 1, 1914 to June 1, 1916, ten carriers were found, that is, 23.25 per cent. of forty-three nurses. About June 1, 1916, the practice of wearing gauze masks covering the nose and mouth when caring for active diphtheria patients was introduced and since then but six carriers have been detected among the seventy-three nurses on duty, that is, 8.2 per cent. Between June 1,

1916, and Dec. 1, 1917, when gauze masks were worn when all patients with scarlet fever in the acute stages were being cared for, no cases of this disease have been observed among the seventy-three nurses on duty. Nine cases of scarlet fever had developed in three years previous to the above dates. In recent years so much emphasis has been laid on contact infection in contagious diseases that the possibility of infection through the air at short distances has been sometimes forgotten. Infection through the air for relatively short distances, that is, within a few feet of the patient (or carrier), is quite possible in case the specific agent is present in the secretions of the nose and throat when forcibly thrown out in small particles in forced expiratory efforts, as in coughing, crying, or sneezing. The masks employed consist of a double thickness of gauze, so shaped as to fit closely over the face from the chin well up over the nose, and held in place by two tapes tied behind the head. A mask is never worn twice until sterilized and washed, and is always replaced by a fresh one when evidently contaminated or when it becomes moist. Most of the nurses wear them constantly when on duty. The attacks of tonsillitis, pharyngitis, and rhinitis that were relatively frequent before the masks were used also have almost disappeared in the last year. Last spring fourteen epidemic meningitis patients were cared for in the hospital. When caring for these patients nurses and physicians always wore masks. Systematic nasopharyngeal cultures, repeated at short intervals, failed to reveal a single carrier of meningococci among the nurses and doctors who took care of these patients. The physicians in the hospital always wear the gauze masks when doing intubations and taking throat cultures, and to a considerable extent when examining patients. Coincident with this use of masks there has been an absence of diphtheria or diphtheria bacillus carriers among the physicians, and only a limited number of throat infections. Weaver favors the wearing of the masks by those coming in contact with cases of pneumonia and epidemic meningitis, especially in those that deal with epidemic outbreaks, such as occur in military camps, gauze masks might be used with advantage by all physicians, orderlies and nurses. The importance of carriers in these diseases is apparently very great, and that those about such patients become carriers quite frequently is evident when not less than 12 per cent. of carriers of meningococci occurred among the personnel of a hospital in which epidemic meningitis patients were treated. The mask not only protects the healthy person from infection and from becoming a carrier, but also prevents a carrier from spreading infection to others. Masks can be used to good advantage also in households in which are patients with diphtheria, pneumonia, scarlet fever, epidemic meningitis, or other diseases spread by nasopharyngeal discharges.

4. A Modern View of Tetanus. Fred Ransom.
5. Analysis of 102 Consecutive Cases of Tetanus Treated at Sir J. J. Hospital, Bombay, India, from October, 1915, to July 31, 1917. Navroji Ardeshir Cooper.
6. On Certain Forms of Albuminuria and Polyuria: Their Cause and Cure. Edgar F. Cyriax.

3. Fifth Analysis of Cases of Tetanus Treated in Home Hospitals During Part of December, 1916, All January and February and Part of March, 1917.—David Bruce gives this report, which is a continuation of the work on tetanus begun in August, 1914. This is the fifth analysis submitted and it shows a decided decrease in the mortality rate, 19 per cent., over that of the first analysis, which gave a mortality of 57.7 per cent. He considers that whatever the cause—the prophylactic dose of serum, better surgical treatment, quicker diagnosis, more thorough therapeutic treatment, etc.—the result is gratifying. In regard to the proportion of wounded men who contract tetanus in

home hospitals, the number may be roughly put down at 1 per 1,000, but since the number of wounded in England has not been published, it is impossible to tell this with exactness. This last analysis deals with 100 cases and shows that if the symptoms of tetanus appeared within ten days of receiving the wound the mortality was 40 per cent.; if from the eleventh to the twenty-fourth day, 25 per cent. The remaining 66 cases, with an incubation period of from 25 to 786 days, averaged a mortality of 13.6 per cent. This last incubation period of 786 days is a doubtful case, according to David Bruce. The man was reported to have had three attacks of tetanus. The last attack, with such a lengthy incubation period, was probably due to a nervous, hysterical condition which was mistaken for tetanus. It has been demonstrated, however, that the tetanus bacilli may remain quiescent for long periods at the site of old wounds, so that 786 days would not seem to be an impossible incubation period. The shortest period of incubation was 3 days, the longest 239. There were only 10 cases with a short incubation period and 69 cases with an incubation period of more than 22 days. Statistics are showing that the average incubation period has been steadily lengthening since the beginning of the war. Bruce attributes this change principally to the prophylactic injection of antitoxin. In the first year of the war there were 47 per cent. of cases with a short incubation, while the last analysis showed a reduction to 10 per cent. In 1914-15 there were only 6.4 per cent. of cases with a long incubation period; this has risen to 69 per cent. During the first year of the war many of the wounded did not receive the prophylactic dose of antitoxin, hence the number of acute cases with a short incubation period. Of the 100 cases under consideration in this last analysis, 81 were classed as cases of general tetanus and 19 as cases of local type. In the 81 cases of generalized tetanus there were 58 recoveries and 23 deaths, a mortality of 28.3 per cent. All of the cases of localized tetanus recovered. There were 6 cases in which tetanus followed on an operation with 1 death. In none of these cases was a prophylactic inoculation of antitetanic serum given before the operation. As a result the Tetanus Committee advises that when operations are performed at the site of wounds, even if they are healed, the prophylactic injection of serum should invariably be given. Among the 100 cases, 73 received a prophylactic injection of serum in France. Twenty-one cases received secondary prophylactic injection; 8 received three injections, 4 received four injections, and 1 received five injections. Of the 73, 60 recovered and 13 died, a mortality of 17.7 per cent. Of the remaining 27 cases, 13 gave no history of prophylactic treatment, 11 of which recovered and 2 died. The remaining 14 cases gave no history of prophylactic injection of any kind; of these 10 recovered and 4 died. In the 100 cases reviewed the mortality was 19 per cent. While but 73 of these cases were recorded as having received a prophylactic injection in France, the whole of them were treated with antitetanic serum. Eighty-one recovered, 19 died, giving a mortality of 19 per cent. The various routes of injection of the antitetanic serum were employed with no definite results as to the advantage of any special route, nor was the influence of the amount of dosage brought to any definite conclusion. David Bruce sums up the results of his fifth analysis as follows: (1) In the 100 cases of tetanus under review the mortality was only 19 per cent. (2) The incubation period tends to become longer, due to the prophylactic injection. Hence there are only 10 cases reported with an incubation of 10 days or under. (3) Only 14 cases are reported to have received secondary prophylactic injections of antitetanic serum in home hospitals. (4) In regard to the therapeutic effect of antitoxic serum the evidence is still inconclusive.

4. Modern View of Tetanus.—Fred Ransom, member of the War Office Committee on Tetanus, points out the fact that the onset of this disease varies considerably in different animals, and for this reason he divides animals, including man, into three classes, according to the form in which the disease commences. In guinea-pigs and mice the first symptoms after subcutaneous or intramuscular injection appear in muscles in the immediate neighborhood of the point of injection, producing what is known as local tetanus. In man and

the horse certain muscular areas are usually first affected, irrespective of the site of injection—in man the masseters and muscles of the neck, in the horse muscles of the neck and tail. This may be called tetanus or *tetanus descendens*. In frogs and fowls the symptoms are general from the onset. The course of the disease depends upon the amount of toxin administered; if sufficient, the local as well as the descending form will develop into more or less severe general tetanus; or if the dose is small the attack will not pass beyond the local or specific phase. Ransom, together with H. H. Meyer, offer the following explanation of local tetanus, as well as the etiology of tetanus as the result of their experimental work on this disease. When tetanus toxin is injected subcutaneously it begins at once to pass from the lymph spaces into the lymph vessels and in a few minutes can be recognized in the lymph of the thoracic duct. It thus reaches the blood stream, not much being absorbed by the blood-vessels direct from the seat of injection. This distribution continues, until in about 24 hours the lymph and the blood contain per cubic centimeter about the same amount of toxin. The result is about the same if the toxin is given intravenously. After neither of these routes of injection can toxin be detected in the cerebrospinal fluid, not even when doses far exceeding the lethal dose have been given. If by means of lumbar puncture the toxin is injected into the subarachnoid space without injury to the pia or cord it passes rapidly into the blood stream, and after the usual period of incubation general tetanus ensues. If, however, the toxin is injected intravenously and immediately afterward the spinal cord is injured by the injection of a drop of normal salt solution, then the general tetanus is preceded by a local tetanus in the muscles corresponding to the injured segment of the cord. If the injection of toxin is made direct into the cord a local tetanus corresponding to the injured cells ensues, and the period of incubation is greatly shortened. If an animal is first protected by the administration of a large dose of antitoxin so that no free toxin can exist in the blood, and then a small dose of toxin is injected into a motor nerve, a local tetanus corresponding to the distribution of the injected nerve results. Injection of toxin into a purely sensory nerve does not cause either local or general tetanus. The conclusion they draw is that the toxin is carried to the central nervous system along the motor nerves. The cells of the central nervous system do not pick up the toxin from the blood or the lymph; the only route by which cells can be attacked is via the motor nerves. Under this condition the toxin traveling along the motor nerves reaches their centers before the rest of the toxin, which has first to be absorbed and distributed, has time to become effective, and the result is a local tetanus. Certain areas can be protected by injecting antitoxin into the motor nerve. The sensory nerve trunks are not implicated in the transport of toxin from the seat of infection or the blood stream to the central nervous system, but they are susceptible if brought into immediate contact with the toxin. Muscular rigidity will not be the result, but hyperesthesia in the sensory areas corresponding to the injected posterior root. This condition Ransom and Meyer have termed *tetanus dolorosus*. They further believe that the transporting medium is the protoplasm of the neurons. The action of prophylactic injections of antitetanic serum has tended to limit this condition to local tetanus, and to remove man from the class of animals predisposed to descending tetanus to that in which local tetanus prevails. The injections do not necessarily prevent the occurrence of local tetanus, because some of the toxin formed at the point of injection is rapidly taken up by the motor nerves in the vicinity and can be effective; but they can ward off general tetanus. The writers consider that under present conditions the occurrence of trismus as a first or early symptom in man is an indication of insufficient or ineffective use of antitoxin as a prophylactic. With reference to the therapeutic use of antitoxin, the toxin in nerves and nerve cells is inaccessible to antitoxin. The only toxin which can be effectively neutralized is that in the blood and lymph; it is not taken up by the nerves, nor does it ever reach the nerve cells. It does not pass in any large proportion into the cerebrospinal fluid after intrave-

nous injection. Moreover, as antitoxin reaches the blood stream quickly from the cerebrospinal fluid, it would, if in excess, neutralize any toxin in the circulation. In the therapeutic use of antitoxin everything depends upon time, and hence the immense importance of careful research for the earliest symptoms and the unhesitating employment of serum upon their recognition. The prompt use of antitoxin may neutralize just that amount of toxin in the blood, which if it reached the nervous system, would turn the balance against the patient. Ransom points out the fact also that in human beings the diaphragm is very early attacked in this disease even before the jaws; then respiration will be to some extent interfered with because the inhibitory relaxation of the muscle tends to be converted into a contraction (pain in the chest).

Therapy of Obstinate Cases of Malaria.—Auprecht, after some discussion of the treatments generally employed offers the following formula for obstinate cases of this infection which he fancies is of some service:

R. Acid, arsenic..... $\frac{1}{2}$ grain.
Quinin. hydrochlor..... 75 grains.
Succ. liquisit, q. s.

for 100 pills.

S. Two pills three times daily.

In the more urgent cases Auprecht reduces the number of pills to two daily and prescribes uridine hydrochloride in the dose of ten grains three to four hours before the expected time of the febrile paroxysm.

Death from Cardiac Disturbance in Diphtheria.—R. Rohmer, giving a summary of his researches carried out during the past ten years on this question, comes to the conclusion that the cause of sudden collapse during the evolution of diphtheritic intoxication should be looked for in the changes arising in the myocardium itself. However, disturbances in the innervation and conduction (the auriculo-ventricular dissociation demonstrated by the phlebogram) may increase the cardiac work and hasten its paralysis. On the other hand, the part played by renal insufficiency is amply demonstrated by numerous clinical and anatomical verifications; it acts by the intermediary of vascular hypotension or by a slowing down of the cardiac contractions. Consequently, the treatment of serious cases of diphtheria should above all include hypodermic injections of adrenalin, which now have a tendency to become general in Germany. The association of pituitary extract will also, according to Rohmer, increase the efficiency of the treatment by prolonging the action of the adrenalin.

The Clinical Aspects and Etiology of Volhynia Fever (Werner-His Disease) (concluded from the issue of October 16.—F. Munk and H. da Rocha-Lima, having studied and carefully examined the lice carrying the germs of typhus fever, have been able to confirm the intracellular development of the Rickettsia-Provazeki organism, the etiological agent of the disease. The Rickettsia met with in patients suffering from this infection and those developing in the lumen of the intestine in the louse are only exceptionally encountered within the cells. In order to put in evidence this differential character microscopic sections must be made, as cover-glass preparations are insufficient to demonstrate the intra- or extracellular situation of the organisms. As to Volhynia fever, the writers do not feel that their researches authorize them to attribute its etiology to the Rickettsia (*R. pediculi* and *quintana*). Besides, the transmission of the disease by lice is not the only way, because the urine likewise is a vehicle of transmission. The virus of the infection survives during the febrile phase of the disease, so that it may very well be admitted that there is a reasonable possibility of dissemination by cured carriers of the virus.

Has War Exercised an Influence on the Composition of Mother's Milk?—Momm and Kraemer have undertaken a series of analyses of the milk of nursing women of the poorer city class, all of whom offered a certain

amount of emaciation due to privation resulting from the war. They found that the milk was, generally speaking, not greatly changed in its composition. The writers offer the following comparative table:

	War-Time.	Normal.
Sp. gr.....	1.0249	1.0298
Water.....	85.41 per cent.	87.58 per cent.
Dry extracts...	13.53 per cent.	12.2 per cent.
Fats.....	3.61 per cent.	3.74 per cent.

Partial Sinoauricular Block in Man.—H. Straub reports two cases of bigeminate pulse. The phlebograms and the electrocardiogram showed that the condition was really an arrhythmia involving both auricles and ventricles. Its site must, therefore, be above the auricle, that is to say, sinusal or sinoauricular. The writer believes that the first named location is to be discarded. The fact that the interval separating two groups of systoles is equivalent to twice the interval of these systoles necessarily offers the following explanation, namely, that the sinus beats normally at the rate of 103 pulsations per minute. Of the three following impulses, only two reach the auricle, the third being intercepted on its way to the auricle. This rhythm of two in three can suddenly become transformed into a bradycardic rhythm, quite regularly struck at at one for two, and this occurred in the second case recorded in the paper. The writer is of the opinion that these phenomena may throw some light on the genesis of paroxysmal tachycardia and permanent bradycardia. He is not inclined to explain the process by changes in a neuromuscular bundle, which for that matter does not exist, but by a disproportion between excitation and excitability in the area of the primitive cardiac tube.

Reactions of Immunity, Produced by the Weil-Felix Bacillus and Their Etiological Significance in Typhus Fever.—E. Friedberger, basing his views on experiments of agglutination, precipitation, the deviation of the complement, on the presence of Pfeiffer's phenomenon, and on the inoculability in the guinea-pig, affirms that the Weil-Felix bacillus is pathogenic of typhus fever. He is decidedly opposed to the theory which attributes this disease to a protozoön developing in the louse and which considers the Weil-Felix reaction as purely secondary. Everything points to a bacterial infection, the agent of which can only be the bacillus of Weil-Felix. For these reasons this organism should be called the bacillus of typhus fever.

Scorbutus at the Front (continued from the issue of October 27).—E. Schindler has endeavored empirically to solve the question of the genesis of scorbutus by giving certain fixed diets for different groups of cases. From his observations it appears that essays in the treatment of this process in the circumstances permitted by the conditions at the front, show that an abundant diet of fruit and vegetables, particularly uncooked (sour kroust, sorrel, lemon or other juice), rich in vegetable acids and aromatic bodies, rapidly cure the process and even act in a prophylactic way. At all events the experiments of the writer are opposed to the acidogenous theory, likewise to the theory of demineralization. The comparative action of the various vegetables has no relation whatever with their content of the various ions (K, Na, Ca). Everything points favorably to the part played by vitamins in preventing the development of this pathological process.

Lateral Radiography of the Sternum.—L. Lilienfeld merely refers to the value and technique of radiograms taken in profile of the sternal region, which requires no analysis of the paper.

Initial Azotemia and Its Prognosis.—Widal, Weill, and Pasteur Valéry-Radot report on some interim work following the publication in 1914 of an essay on azotemia. A number of cases of Bright's disease originally studied have been followed up. Much has been learned

about the significance of blood urea when the latter exceeds 1 gram per liter, and the authors have transferred the problem to the initial phase of azotemia when the blood urea ranges between 0.5 and 1.0 gram per liter. This low figure corresponds also to minor azotemia, and in its consideration certain outside factors have to be borne in mind, such as the intake of protein food, the intake of chlorine, the presence or absence of edema, the state of diuresis, and perhaps other factors. All of these elements must be removed or discounted. Minor or initial azotemia may be expected under a variety of circumstances aside from progressive cirrhotic processes; for example in acute nephritis, including so-called war nephritis; while it also may come and go in chronic nephritis under similar conditions, i.e. there is a tendency to acute exacerbation. Hence azotemia may not be progressive but regressive, and allowance must be made for such behavior. As the regressive type is transitory, such cases can be made to exclude themselves. On the other hand an azotemia of more than 3 grams per liter presents no problem, for the patient has not long to live; and one between 2 and 3 grams per liter is hardly a problem, for the individual patient will very likely succumb in a few months, perhaps in a few weeks. When the azotemia is between 1 and 2 grams per liter the problem consists in securing for the patient the year or so of life which may be coming to him; for if his blood pressure be not controlled he may die suddenly from some accident, and this likelihood is by no means absent in azotemia below 1 gram per liter. Generally speaking, a blood content of urea below 1 gram per liter, but not less than half a gram, presents a complicated condition for reasons already stated. It may mean a stationary lesion, as in a case stated in which during four years 1 gram per liter was never exceeded. Or it may mean an intermittent evolution in which the initial azotemia disappears for a given period only to return in a less degree. In a third type we see oscillations about the half-gram mark, while the fourth type is progressive throughout. Hence, by the term initial azotemia the authors do not imply a condition in its first stage which is bound to grow worse, but rather a condition which may regress, remain constant, intermittent, or become progressive. It is a danger signal.

Two Cases of Cancer of the Stomach with Initial Diagnosis of Malaria.—C. Rovsing reports cases as follows: 1. Male, 47; history of beriberi and malaria; admitted to Th. Rovsing's private clinic with diagnosis of latter. There was a crisis of fever every third or fifth day. During several years previous he had suffered—following hospital diagnoses—from staphylococcus sepsis, hematuria, and pyelitis. A study of the stomach chemistry led to a diagnosis of pyloric stenosis, possibly cancerous. The only symptom which appeared to implicate the stomach had been attacks of vomiting, which stood in some relationship with the fever, being followed by defervescence. No tumor could be palpated. Laparotomy revealed a large mass in the stomach wall without extragastric extension or metastases. Resection was performed by Polya's method with good recovery. Case II closely resembled Case I. The patient was a man of 49 who for some years had suffered from recurrent attacks of fever which subsided after vomiting. Fever was continuous for 4 or 5 days and was not controlled by quinine or arsenic. The spleen was somewhat enlarged and anemia was shown of blood counts. Tests of stomach contents showed retention and a diagnosis of pyloric cancer was made, confirmed by operation. The patient succumbed from recurrence. Neither of these patients had presented digestive disturbances, and there had been no reason for suspecting the presence of cancer. The association of gastric retention with fever and finally vomiting with defervescence is rare in literature. A "five-day fever" associated with stomach cancer was noted by Halla in 1844, while Hampeln reported cases much like the author's later in the same year. In 1889 Bühring wrote a thesis on intermittent fever in the course of cancer of the stomach.

Book Reviews.

THE PRINCIPLES OF GYNÆCOLOGY FOR STUDENTS AND PRACTITIONERS OF MEDICINE. By BLAIR BELL, B. S., M.D., Lond. Gynecological Surgeon, Royal Infirmary, Liverpool; Lecturer and Examiner in Clinical Gynecology in the University of Liverpool; Sometime Examiner in Gynecology and Obstetrics to the Royal College of Physicians and Surgeons, England, and to the Universities of Durham and Belfast; Arris and Gale Lecturer, and Hunterian Professor, Royal College of Surgeons, England. Second Edition. Large octavo of 551 pages with 363 illustrations. Price, \$6.50. New York: William Wood and Company, 1917.

WHILE this book has been revised wherever it seemed necessary, the author frankly states in the preface that the alterations have been comparatively few for two reasons: first, because recent additions to our knowledge required only occasional changes in the text; and, second, because of lack of time to rewrite extensively on account of war conditions.

Fortunately, this is a book that required but little change owing to the unusual excellence of the former edition. Here we have a work that follows a plan far different from the usual track. It is not a compilation, but is a practical book based on the author's extensive experience, and describing the methods he has found most useful. Much stress has been very properly laid on the value of a thorough knowledge of gynecological physiology, anatomy and pathology; for certainly without such a knowledge intelligent treatment is next to impossible. Besides excellent descriptions of the various pathological processes that affect the genital apparatus, there are numerous illustrations and photomicrographs showing the gross and microscopical pathological anatomy. Numerous illustrations are also called to the aid of the text in connection with the descriptions of the normal appearances of the genital structures, forms of treatment and operative technique.

To give a firm foundation for the study of the subject, nearly 100 pages are first devoted to the development, normal anatomy and physiology of the genital organs. Methods of examination are next discussed and illustrated, then the various congenital and acquired conditions which one meets in gynecological practice are taken up in logical sequence. Finally, there are chapters devoted to the preparation for operation and after-care of the patient, and to the description and illustration of the technique in the more common gynecological operations, both vaginal and abdominal. In the Appendix there is a short chapter on electrotherapeutics in gynecology which is contributed by J. Curtis Webb, and a chapter entitled: "Classification of the Causes of Certain Symptoms." This latter, if properly used, should be of much value.

The book is well printed and bound, the numerous illustrations are almost uniformly excellent and to the point, the text is lucid and well written, as well as being authoritative, and as a result the book can be unhesitatingly recommended for use by both student and practitioner.

A TREATISE ON ORTHOPEDIC SURGERY. By ROYAL WHITMAN, M.D., M.R.C.S., Eng., F.A.C.S., Assistant Professor of Orthopedic Surgery in the College of Physicians and Surgeons of Columbia University, New York; Professor of Orthopedic Surgery in the New York Polyclinic Medical School and Hospital; Associate Surgeon to the Hospital for Ruptured and Crippled; Orthopedic Surgeon to the Hospital of St. John's Guild; Consulting Orthopedic Surgeon to St. Agnes' Hospital for Crippled and Atypical Children, White Plains, to the New York Home for Destitute Crippled Children and to the New York State Board of Health; Member of the American Orthopedic Association; Corresponding Member of the British Orthopedic Society; Member of the New York Surgical Society, etc. Fifth edition, revised and enlarged. Octavo of 906 pages illustrated with 704 engravings. Price, \$6.50 net. Philadelphia and New York: Lea and Febiger, 1917.

WHITMAN'S book is a real orthopedic surgery and not a mere compilation of pathology, signs, and symptoms of orthopedic conditions with exhaustive directions for the application of plaster and braces and with occasional brief suggestions for real surgery. The author

has done much for the advancement of his specialty. He has originated methods of treatment and devised operative procedures that have been accorded almost general acceptance, though sometimes rather tardily and apparently rather grudgingly on the part of some of his confrères. In addition to this, Whitman has been a close student of the literature of his subject, has had many years' experience as a teacher of both undergraduate and postgraduate students, and possesses distinct literary ability; hence it is not surprising that his work has already reached a fifth edition and that we can classify the work as a real orthopedic surgery.

As the author remarks in the preface, the recent epidemic of anterior poliomyelitis and the crippling accidents of war have enforced a general recognition of the importance of orthopedic principles as applied both for prevention and "reconstruction." The book has, therefore, been carefully revised with the purpose of presenting the broader aspects of orthopedic surgery in scope and detail as defined by its literature and by the work of representative clinics in this and other countries. He also calls attention to the fact that the most distinct advance of orthopedic surgery in recent years has been toward the prevention of deformity. These principles have been kept in mind, and the result is a book that reflects current opinion and current practice perhaps better than any other in this field.

However, the chapter entitled "Military Orthopedics" is a great disappointment. The small space (12 pages) devoted to this subject—a subject of world-wide interest now and for many years to come—is woefully inadequate; and we feel that the chapter might almost as well have been omitted entirely. Possibly the author felt that detailed exposition of this phase of the subject should be left to those having greater experience in this particular field, or until he himself has had greater opportunities for observing and treating a sufficient number of cases; but, whatever the reason, one would hardly think that the author of this puny effort could be the same man who has written so admirably and at times brilliantly on the subjects covered in the remainder of the volume.

TALKS ON OBSTETRICS. By RAE THORNTON LAVAKE, Instructor in Obstetrics and Gynecology, University of Minnesota; Obstetrician-in-Charge of the Out-Patient Obstetric Department of the University of Minnesota, etc., etc.; One Time Assistant Resident Obstetrician to the Sloane Hospital for Women in New York. Price, \$1. St. Louis: C. V. Mosby Company, 1917.

THIS little book suggests a quiz or pocket compend, but is not intended for either purpose. Dr. Litzenberg, the author's superior in the teaching body of the University, contributes a brief introduction in which the volume is classed as unique. It consists of thirteen chapters on special features of midwifery practice, including sepsis, toxemias of pregnancy, hemorrhage, forceps, podalic version, occipitoposterior positions, face presentations, cesarean section, etc., etc., with an additional chapter on Rules in Obstetrics. Placenta previa is considered under hemorrhage and eclampsia under toxemias so that more ground is covered than at first sight appears.

TROUBLES MENTAUX DE GUERRE. Par JEAN LEPINÉ, Professeur de Clinique des Maladies Nerveuses et Mentales à l'Université de Lyon. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1917.

THE clinical section of the work deals with acute, chronic, and special affections. Under the first named are considered confusional, depressive, and commotional states, acute organic diseases, and alcoholism. Under chronic affections we find various forms of dementia, including paresis and chronic confusional and delirious states. Under special affections are discussed the mental symptoms of chronic organic diseases (excepting paresis) and of epilepsy, hysteria, and psychasthenia. The second section of the book deals with the forensic aspects of war insanities in respect to desertions, arson, theft, simulation, etc. Seven types of individuals require consideration in respect to the value of their testimony. A special chapter is devoted to the management of these men. A work like this should have many bearings on insanity and psychiatry in general and should cause some modification of prevalent views, especially in regard to commotional syndromes.

Society Reports.

THE AMERICAN CONGRESS ON INTERNAL MEDICINE.

Second Scientific Session, Held in Pittsburgh, December 27 and 28, 1917.

DR. REYNOLD WEBB WILCOX, PRESIDENT, IN THE CHAIR.

(Concluded from page 87.)

Friday, December 28—Second Day.

Some Problems of Cardiovascular Disease.—Dr. EDWARD E. CORNWALL of Brooklyn, N. Y., read this paper. The author stated that the central pumping system, including the tubes, might be subjected to unusual wear and tear. This system with its dependent branches might be considered as a whole; and looked upon in this way its defects need not be necessarily denominated "arteriosclerosis," nor "chronic nephritis," nor yet "myocardial disease"; these were merely pathological manifestations in the principal foci, so to speak, and could not each be considered as a clinical entity. The damage to the pumping system as a whole presented many problems, but the speaker would confine his discussion to two of them—heredity and prophylaxis. Prophylaxis in this condition deserved more attention than it generally received at the hands of the profession. Cardiovascular disease, the author stated, was as important in the second half of life as bacterial disease was in the first half. The loss to the world, by the premature shortening of useful activities was undoubtedly greater. Among etiological factors, heredity played a prominent part. The quality of the pumping apparatus was inherited, just in the same way that a constitutional susceptibility to tuberculosis might be said to be an inheritance. An inherited metabolic insufficiency was often a pathological condition predisposing to cardiovascular disease. Apoplexy, diabetes, gout, heart disease, obesity, chronic headaches were all factors often to be noted in the heredity of patients whose vascular apparatus showed early signs of wear and tear. Many, by adopting a certain modified mode of life, escaped the consequences of such an heredity. Excessive work, either physical or mental, was one potent factor in producing early degeneration of the vascular apparatus. Late hours and excitement forced the cardiac apparatus to maintain permanent arterial overpressure. The immense task of transforming material from the outside world into suitable agents for nutrition of the body was laid upon metabolism, as also the elimination of the waste products. The poisons of infectious diseases—syphilis, rheumatic fever, typhoid, laid a heavy burden on the system, and often did permanent damage to the circulatory apparatus. A very common cause of damage too was chronic poisoning by tobacco, alcohol, or caffeine. Thus it might be stated that *easy life* and *easy diet* were essentials in dealing with these cases. The term "easy life" needed no further elucidation. The term "easy diet," however, was not so easy of explanation. Modern life had changed the habits of the organism in one or two generations from the natural, simple country life to the artificial life-under-strain of cities, with a resulting great increase of deaths from cardiovascular disease. Therefore, the "easy diet" must reduce to a practical minimum the work of the organism in feeding and fueling itself, and in cleaning out the furnace. There must be quantitative as well as qualitative regulation. Different articles of food might have the same proportions of food elements, but, from the point of view of their consequences in the body, they might be very different. Thus spinach and cabbage; or again, dextrose and saccharose, had the same constituents, yet differed widely in physical value. Lean beef, milk, eggs might have the same amino acids, yet in their by-products might produce a very different effect. In some proteins the broken down products were subject to putrefactive action in the intestine; others were susceptible to the action of acid-forming bacteria; these latter, which soured on spoiling, such as milk and cereals, did not load the body with products of putrefaction. However, the body became accustomed to battling with a certain amount of putrefactive poison, so that a

certain amount of such proteins could be used. In this connection it could be said vegetarianism did not meet the needs of the body. To quote Holy Writ, "Man cannot live by bread alone . . ." By thinking in terms of amino acids—in what the body needed without losing nitrogenous weight, it was found that vegetables did not correspond to the body needs. Perfect proteins, in terms of amino-acids, were animal flesh, eggs, and milk. Milk contained the amino acids in a desirable form. Thus, while vegetarianism was not suited to body needs, a lacto-vegetarianism was possible, although a small amount of meat was permissible. The author further stated that the symptoms of arteriosclerosis were simply nature's efforts to counteract existing damage. Sometimes nature lost control and overdid her efforts. Only where pressure was high enough to injure the system, was treatment indicated. All other efforts should be directed toward removing the conditions which make treatment necessary; and the most important part of this treatment was the "easy diet."

Dr. R. W. WILCOX of New York said that it was a little dangerous for a speaker to quote Holy Writ. Another quotation might be found to refute the first. He believed that there was one individual mentioned in the Bible who subsisted seven years on grass. Nebuchadnezzar was the name of this person. Dr. Wilcox said that he was interested in the question of vegetarianism. Very few persons were really true vegetarians. He knew of one man, a physician, who was a strict vegetarian, and it was remarkable to note in this connection that the more nearly the person approached a non-animal diet, the more sweets they were apt to consume. They were also apt to be inordinate users of tobacco. So-called vegetarians often consumed a considerable number of eggs in their diet. In Europe there were many vegetarian restaurants, but the only really palatable article they offered was chocolate, which was frequently really delicious, and the only excuse one would have for patronizing them. The speaker said he wished to express appreciation of Dr. Cornwall's scholarly paper and he hoped the response by discussion would be generous.

Dr. C. EVERETT FIELD of New York said that he considered this subject to be of tremendous importance. They should all appreciate Dr. Cornwall's scholarly presentation of the subject. In his own work, as director of the Radium Sanatorium in New York, his attention was constantly called to the study of cases in this condition. The Germans had written for ten years on the value of radium in internal treatment, and the cases sent to them were those of diet, where all known treatments had failed. Many cases ran a blood pressure of from 180 to 240, with extreme kidney or heart lesions. It could be said that if any result was obtained from the administration of radium, it came from the action of the rays on the body metabolism—that is the body ferments. Even with the tiniest dose of radium water there was an enormous increase of solids in the urine, with corresponding vascular dilatation. It is true that the pressure should be slowly and gradually brought down, but where one could bring about an improvement in the action of the kidneys, dilatation was a safe procedure. The patient might have been on an extremely restricted diet for 6 years and yet the blood pressure could be brought down 30 points. These results showed a fair permanence. Dr. Field said he had noted continuance of results after 3½ years. The importance of these conclusions was enormous. The number of active business men who were going down daily with cardiovascular disease was appalling. The first symptoms of degeneration of the cardiovascular system must be studied. As Dr. Cornwall had stated, if one could head off the first beginning of degeneration, the changes in the valves before degeneration started in the blood vessels, then it could be asserted that the profession had solved one of the most important problems of internal medicine that it had ever dealt with.

Dr. TICE of Chicago said that it would seem at the present time that the question of diet was of the utmost importance in dealing with cardiovascular disease, which was, in turn, closely associated with the question of *tonus*, or cardiac power. Diet played a large part, both in the production of the disease and in the restoration of cardiac efficiency. An important point was the

reserve power of the heart and its ability to return to tonus. The question was not so much as to whether the actual disease was myocardial or aortic, but what was the functional ability still possessed by the heart. This again hinged not only upon the question of actual change and vascular capacity, but also upon whether or not the heart was receiving the proper amount of nutrition. Whether this was to be corrected by the regulation of diet, or whether it was to be corrected by attention to other metabolic disturbances, by increase of elimination, by radium therapy, mechanical therapy, or any other one might use. The whole thing rested upon the reestablishment of cardiac tonus, which practically meant cardiac function.

The president said he would like to suggest a correction to the first speaker, who had said "cardio-vascular dilatation." Presumably he meant "vascular dilatation."

Dr. BAAR of Portland, Oregon, said that the first thing radium did was to cause leucocytosis. Whether the increased leucocytosis had anything to do with increased metabolism, and thereby elimination of toxins and consequent prevention of arteriosclerosis was as yet purely a speculative question. When one asked if radium stimulated enzymes and hormones, one was surely dealing, as yet, with abstract metaphysics. So far as one knew there was leucocytosis and nothing else. He thought internists must stick to what they really knew. Leucocytosis was still as much of a conundrum as it was 2000 years ago. One could not say anything new about it.

Dr. BARAC of Pittsburgh said he would like to touch upon one or two important points. For the last 12 or 15 years he had been specially interested in the subject of cardiac hypertrophy. He would like to bring to the minds of those present the fact that efforts at cardiac compensation occurred frequently in adolescent boys and youths of college age. One did not have the opportunity to study girls at this age so much, but in boys it was perhaps the result of increased muscular activity. Often in these subjects, up to and during the college age, one found the apex prominent and there was an increased area of dullness, although one did not state that a boy had an hypertrophied heart because the dullness went beyond the average limits. This might be only functional and not pathological. The speaker had had an opportunity to see many college boys and in the Carnegie technical schools from 3000 to 5000 were examined every year and frequently there was found a condition of cardiac hypertrophy. In regard to athletics, Dr. Barac said the men who trained for the Marathon race of 25 miles were in training 5 months of the year. These men showed increased blood pressure and enlarged hearts on physical examination. In these cases there was a true hypertrophy. Shortly after the maximal effort, many of them showed broader hearts with symptoms of dilatation. Within a few weeks many of these hearts returned to the normal size, so that as soon as there was relief of the excessive strain the condition disappeared. This showed that the hypertrophy was in response to the demand of the organism. One man who came to the speaker for 15 years had been in the practice of keeping in training to run 25 miles, for no other reason than that he thought he was smart to do it. This man had a permanent hypertrophy of the heart. Another thing that was apt to happen when these college boys ran 5, 10, or 15 miles, was that most of them come back showing albumin, red blood cells, and even casts in the urine. This condition could be produced within five minutes after commencement of the effort. It was not surprising that casts could be thus produced by excessive effort for a few minutes, but the point to be borne in mind in connection with this sign was that an albuminuria might be very transient and when a patient came into the office with this symptom, it did not necessarily follow that it was a serious condition. The history of medicine after the Civil War showed that there were many cases of damaged hearts. One wonders if there would be any interesting and startling results recorded now in the army, as many men who had lived sedentary lives would be obliged to undertake long marches. It was probable that many of these would show enlarged hearts and many latent weaknesses would be developed. There was a class of cases

which came in the hypertension class. These patients exhibited all the symptoms of hyperthyroidism. They had the nervous symptomatology, sugar in the urine, and exophthalmos, associated with hypertension. After ten days or so of treatment by rest in bed, a remarkable change was brought about in the nervous condition. They no longer showed signs of the "excessive kinetic drive" of Crile. This class of patient was remarkably amenable to treatment and breaking the vicious circle would produce a remarkable improvement in the state of hypertension. During the past few years the speaker said he had noticed several patients of the large, obese type, having a low blood pressure—110 systolic; they also had albumin and casts in the urine. These cases had rapidly, that is within a year, progressed to the stage of hypertension, 160 to 180 systolic pressure, which showed how quickly the hypertension might develop. These symptoms were apt to have their beginning in early college days, but in middle life they developed very rapidly.

Dr. BAAR of Portland, Oregon, said that one could have some very interesting speculative ideas in regard to this matter. He had not seen the matter published anywhere of which he would speak. A year ago he noticed a man 70 years of age, who had had a prostatectomy done. This man had a blood pressure of 140. A week after he left the hospital Dr. Baar took his blood pressure and found it to be 240, but there were no subjective symptoms at all, no albumin, no casts, absolutely nothing pathological. The man was treated with prostatic tablets, and the pressure dropped to 170 and stayed so. He wished to mention this for the sake of priority, not because one could prove any definite connection with the subject on hand.

Dr. A. CAILLÉ of New York said he would like to express his appreciation of Dr. Cornwall's presentation. The writer had approached the subject from a point of view that led one to hope that the medical profession was at last getting away from "tinkering." A slight improvement in nomenclature might be suggested; he would prefer the term cardiovascular diathesis, instead of cardiovascular disease; that, however, was a minor point. As to the importance of a restricted diet, he fully agreed with the speaker. A carbohydrate diet, with milk derivatives, was indicated in these conditions. He would like to say a word about high blood pressure. He understood Dr. Cornwall to mention that the adjustment of diet and vasodilators were indicated. He, Dr. Caillé, had found that a venesection, done two or three times a year, would carry these patients on for many years, and could afford considerable comfort, without much trouble.

Dr. IVES of New York said that he wished to discuss this paper from the standpoint of food and metabolism only. He felt that when they went into the question of amino-acids, they were getting somewhat beyond their depth. Speaking in terms of eggs, meat and milk they could work their conclusions out clinically. It must be remembered that not all of these patients with cardiovascular disease were adults, and therefore it was not always a case of faulty metabolism and high pressure. Some of the problems had to be considered from the point of view of toxemia. There was always some damage to the cardiovascular tract in infectious disease. The doctor spoke of rest—rest was an imperative factor for a much longer time than during the actual illness. From the standpoint of high pressure, mention had been made of prostatic tablets. In senility it was to be remarked that there often occurred a low pressure, a hypotension. With these patients one should advise a course of thyroid or pituitrin, and the pressure curve would respond beautifully. This showed that there was something depressive in the lack of internal secretion, even with cardiovascular disease. A course of thyroid or pituitrin would restore the patient to normal health.

Dr. HEINRICH STERN of New York said that the alimentary tract of the occidental human being was not fitted to elaborate completely the vegetable nutrients or their contents. They must not forget that in the oriental races such as the Japanese—a much smaller race—the alimentary tract was from 3 to 6 feet longer than in the European. This extra 3 to 6 feet undoubtedly served some special purpose in metabolism. According to experiments made in Tokio there was no diet

more suitable to the Japanese than the one they were best fitted to elaborate. He understood that the Japanese did not use milk at all, nor did they make use of milk derivatives, including butter and cheese.

The President said that he was interested in the reference to "tinkering" in medicine. He would like to refer to the use of the sphygmomanometer in clinical medicine. In the examination of 1,300 men, veterans of the Civil War, a very frequent symptom that was observed was an extremely low blood pressure. At the same time there were a great variety of serious forms of heart disease. It was unnecessary in a society of this scientific prominence to observe that the sphygmomanometer was of no more and no less use or importance than the clinical thermometer. High or low pressure was not to be considered *per se*. It merely afforded an opportunity for investigating as to the cause thereof. It was to be hoped that the object of this organization would be to stop "tinkering" and get to the bottom of things. This paper of Dr. Cornwall's showed that they were fulfilling their mission as internists.

Dr. E. E. CORNWALL, in closing, said that there were very many interesting points which had been brought out by the discussion. In the first place, as to the name cardiovascular disease. It was, he admitted, a clumsy name, but it meant a wearing out, a clinical syndrome. Other names were much better perhaps—cardiovascular renalism would be a better term, but one had become accustomed to the other and it was understood to express the general syndrome. As to Dr. Baar's remark about their having learned nothing in 2,000 years about leucocytosis, he could not quite agree with him; we had learned the name at least. In regard to the use of dilators, anything like the use of dilators was absolutely wrong in the majority of cases. They must understand that these symptoms were a manifestation on the part of nature that she was trying to compensate the damage. It was when nature overdid her part and injury was threatened to the vascular structure, then and then only had they any right to use the artificial methods of relief and to save the rest of the organism at the expense of the mechanism. He felt that the use of dilators was a great deal overdone. As regards venesection, that was a mighty good thing to do sometimes. It had saved lives many a time. When there was a low diastolic pressure an artificial dilator should never be used. In regard to amino-acids, which had been spoken of in a somewhat slighting tone, this was merely a way of expressing the amount of digestive proteins in the proportions required by the body. The vegetable proteins could not be as conveniently used in body metabolism. As to vegetarians, those who ate eggs were not strict vegetarians. In regard to the length of the alimentary tract, no doubt a shorter alimentary tract required a little meat, but the tendency today was to eat too much. A certain amount of meat was useful. A person born with a constitutional predisposition to gout, apoplexy, Bright's disease or cardiovascular disease should take a low animal protein diet. The phenomenon of low blood pressure being seen in old persons was not unusual. It was frequently seen in such persons as were comparatively healthy and getting along very well. There were one or two factors perhaps which produced this symptom. The first was chronic tobacco poisoning. This would lower the systolic pressure. Second, an intestinal toxemia would sometimes lower the blood pressure, though this depended on the type of bacterial poison. A colon bacillus toxemia would raise the blood pressure, at least it did so in animal experimentation. Thirdly might be mentioned a constitutional habit. Many of these old people got along very comfortably.

The Relationship of Infection in the Production of So-called Pernicious Anemia and Its Significance with Respect to Treatment.—Dr. FRANK SMITHIES of Chicago read this paper. He said that before treatment of this disease could be suggested it was necessary that the nature of the affection should be understood. The treatment was then to be directed toward the restoration of normal functions. Since the first studies of the disease, in 1822, up to the present time, the nature of the affection had been found obscure and the regime had been one that was merely harmless to the patient.

The disease progressed in a more or less self-regulated fashion toward a fatal conclusion. The question to be asked first was what was pernicious anemia and what was not? Any progressive, chronic anemia should be classified as pernicious. Addison's conception of the disease should be appreciated, and it could be considered as identical with Biermer's progressive anemia. They both represented processes in the blood picture attributable to unknown causes. A secondary anemia was supposedly due to known causes, but there was no hard and fast line that could be drawn between the two. One was apt to merge into the other. An idiopathic anemia was distinct from Addison's anemia, which was essentially a hemolytic anemia, specific, chronic in course, and closely related to sepsis. It was due, doubtless, to hemolytic organisms with selective action for the lymphoid tissue. Hunter's theory was that various organisms such as *Streptococcus longus*, or *Streptococcus viridans*, might undergo changes in virulence and be responsible for the condition. The character of the disease might be chronic, or it might be acute. The chronic form, or Addison's anemia, was the most frequent. In the chronic type in the later stages there might be a gastric leucemia, spinal changes, disturbances of sensation, and psychic upsets. Pyorrhea was often an accompaniment. The acute type was characterized by delirium, a semiconscious state, extreme blood changes, the hemoglobin being sometimes as low as 18 per cent., and the coagulation time, 8 minutes. This type was infrequent. A typical case of this kind could be cited. The patient was a young woman, brought to the hospital on a stretcher in a semiconscious, delirious state. Three months before she had been in perfect health, robust, and well-nourished, and had been considered a prize country beauty. She had suffered from an attack of grip with sore throat. A swelling then appeared below the left ribs and the hemoglobin steadily diminished. In this case a hemolytic coccus was isolated from the throat and tissues of the spleen and gallbladder. In this, as in other such cases, the blood was watery and greasy, coagulation time was prolonged, there was variation of the iodine and cholesterol content, and increase in fatty acids which were highly toxic; there was considerable fatty degeneration of the nonstriated muscle. Accompanying these cases were frequently found lesions in the mouth, tonsils, nasopharynx, teeth, and alveolar processes, and an advanced glossitis with invasion of the lymph spaces of the tongue by hemolytic streptococci. Gastrointestinal lesions in this disease were of the ulcerative type. There was early hypertrophy, followed by atrophy and bacterial invasion of the muscle bundles of the walls of the intestine, resembling croupous ulceration. Rosenow's method of culturing bacteria from the tissues would often show hemolytic streptococci, colon bacilli, or *Streptococcus viridans*. In the liver would be found a great increase of blood-derived pigments. The bone marrow first showed megaloblastic hyperplasia, followed by aplasia. In Addison's anemia the spleen was enlarged and congested, and there was considerable perisplenitis. Hemolytic cocci were frequently found in the spleen tissues. In this connection it should be stated that the major function of the spleen had yet to be discovered. It had, no doubt, a protective action and prevented excessive stimulus by the bone marrow. Some workers thought that the destructive action by the spleen proceeded faster than blood construction, and that the spleen became hyperplastic in consequence. One thing could be stated, however, that removal of the spleen was not a cure for the disease. In regard to the problem of treatment there were fundamental points, namely: (1) to bring the serum to normal; (2) to stimulate antibodies, or lysins to counteract the absorption of toxins; (3) to stimulate red-cell production in the bone marrow; (4) to improve the patient's general state and prevent absorption of putrefactive products of digestion; (5) to insure protection of red blood cells by removal of hemolytic cells. In regard to the first point, sometimes saline infusion was found beneficial, as it destroyed inimical constituents in the blood stream, but the writer preferred introduction of whole blood. Requirements for the donor were a negative Wassermann; that he should not recently have had any infectious disease, including tonsillitis; that he should be in good physical

condition. A near relative was not chosen on account of the possibility of a family tendency to the disease. Successful transfusion gave the bone marrow a chance to rest, rather than stimulated its productive energies. In regard to the diet of the patient, it should be limited in respect to proteins and fats, as there was generally a pronounced achylia gastrica. Renal activity should be stimulated by water. The heart could be favorably affected by rest in bed. Fresh air and sunlight were indicated as much as possible, with proper protection from sunburn and cold, as these patients suffered sunburn easily. In conclusion the reader said that 51 exploratory laparotomies had been done in order to discover the focus of infection. In some cases this was the spleen, in some the liver, the gall-bladder, or the appendix. Hemolytic cocci were found in the tissues. The infected organ was removed. After the removal of the focus patients improved out of all proportion to the blood picture. Fifty-six per cent. of cases had been restored to normal. Active life had been resumed for periods varying from 7 to 51 months. Favorable prognosis was in inverse proportion to the amount of damage done to the system. In those cases in which spinal cord changes had already occurred, little or nothing could be done.

THE PRESIDENT said that there was a clinical symptom which these patients presented which was noted by Addison, and which had not escaped the observant eye of Dr. Smithies, namely, mental deterioration. This did not proceed *pari passu* with the blood picture. It was, however, a matter of great importance occasionally as it might occur in the course of a judicial inquiry. This was an excellent paper, and called for free discussion. There were many points in it which had not been enlarged upon owing to lack of time. One point that might be justly called "tinkering" was treatment by splenectomy, *per se*.

Dr. BARAC of Pittsburgh said he believed this was one of the first indications they had had that physicians were getting down to the underlying cause in pernicious anemia. They had been wandering in a maze without knowing where to go. Now one could see that infection was a very likely source of the trouble. It had been lately recognized that infection round the mouth was a probable source of much trouble. Efforts had been directed toward the removal of pyorrhea, which was a frequent accompaniment in these cases. The picture of the tongue in pernicious anemia was characteristic—the red, beefy, smooth, cracked tongue was a prominent symptom. Relapses were always associated with ulcerations of the tongue. He said he had touched these ulcers with nitrate of silver, not because he thought it a good thing, but because he did not know what else to do. Dr. Barker's discussion of pernicious anemia was based on general lines of hygiene, the supply of hydrochloric acid, and intestinal antiseptics. Dr. Smithies had given them something more tangible to work upon. It might be added that in certain cases treatment directed against infection seemed to have done some good. Intravenous injection of salvarsan, which perhaps acted as an antiseptic on the bacterial side, had been of use. He had seen remarkable results in some cases. There was a marked reaction and rise of temperature. He thought there must be a great deal of truth in the theory of infection. If treatment were followed along this line one would get surprising results.

Dr. FRIEDMAN of New York said he had not had experience with acute pernicious anemia. He had observed cases for from 8 to 10 years. Everyone knew that in pernicious anemia there occurred blood crises, especially in the initial stages; on one examination one would find a typical picture, and one month later the picture would be questionable; for instance, megaloblasts would not be found. Improvements in the blood picture could occur even without treatment. He did not know why the blood picture did not remain constant. It never impressed him that splenectomy could benefit the patient because the enlargement of the spleen was certainly a secondary condition in pernicious anemia. In hemolytic jaundice, due to hypersplenism, this really might be of service. He had a patient who was well for two years after splenectomy for hemolytic jaundice. The two conditions were different. In pernicious anemia enlargement of the spleen was not

so pronounced as in other conditions. Extension of the spleen below the umbilicus was rare. The primary condition was not in the spleen or in the bone marrow. As to the infectious nature of the disease he thought Dr. Smithies has produced good experimental evidence in his cases. One was accustomed lately to attribute all latent infection to the tonsils, but one should also consider gastric ulcer, duodenal ulcer, appendicitis, and poliomyelitis. The profession would soon be looking for the primary site of all these infections, which used to be considered the tonsil. If these cases of pernicious anemia could be attributed to infection the discovery would be of great importance to preventive medicine. In regard to achylia gastrica, he had never seen pernicious anemia without this symptom. If there were no achylia, diagnosis should be made with great reserve. Some years ago he had a case with typical picture of pernicious anemia—normoblasts, megaloblasts, enlarged spleen, etc. The man was seen at the Roosevelt Hospital, and they refused to make a diagnosis of pernicious anemia there because achylia gastrica was not present. It seemed then that this symptom was necessary to complete the diagnosis.

Dr. BAAR of Portland, Oregon, said that if he had had nothing else to repay his trip he would have been abundantly compensated by listening to this paper, from which he had learned very much. He had gotten the same results, but in addition he had always observed a constant indicanuria, as well as the achylia gastrica. This had always given him the clue. If he did not find that the case fell into the other category mentioned by Dr. Smithies. In one case, in a boy of 19, with enlarged spleen and liver, and tender gelatinous swellings of the glands, he had tried salvarsan injections. The hemoglobin improved from 30 to 75 per cent., and all swellings subsided except the parotid swellings. Later the patient had erysipelas, from which a streptococcus was recovered. Then he had a focus of infection in the sphenoid. He took a vaccine treatment. Then a purulent iritis broke out. He had the same coccus in the blood, the parotid, and the nasopharynx. He had a pronounced indicanuria. As this disappeared, the patient's hemoglobin percentage rose. In another case of supposed pernicious anemia in a woman, perforation of the nasal septum was found. Salvarsan cleared up the condition, which was congenital syphilis. The immense value of the "cocci" statement must be appreciated. He did not think it was a case of looking for microbes in the tonsils. They were there, undoubtedly, in many cases. Some of the anemias were undoubtedly syphilitic.

Dr. W. H. MERCUR of Pittsburgh stated that he felt interested in the statement of Dr. Smithies as to the performance of 51 laparotomies in this disease. There was a general impression that splenectomy was the cure for this condition. Splenectomy was only a cure when the spleen was the focus of infection; in other words, if the appendix or the gall-bladder was the point of bacterial infection, taking the spleen out would not cure the disease. Osler, some years ago, in a case of pernicious anemia, said "look at the mouth." The patient had decayed teeth. They learned then to look for trouble with the teeth. In regard to transfusion in these cases, one point advocated by Percy would be of value. One might take all precautions to prevent hemolysis and still it could occur and cause serious trouble. Percy would take a small quantity, 0.5 c.c. of blood, and introduce that. If it caused hemolysis the donor was unsuitable. This half cubic centimeter would cause trouble in 10 seconds, if at all; and the introduction of 300 c.c. of the same blood, if unsuitable, would cause much more trouble. Personally Dr. Mercur said he had never seen cases of pernicious anemia get well. Dr. Smithies had stated that 26 cases got well and remained so for from 6 to 51 months. The speaker saw the woman referred to as the longest case. She certainly looked robust and in perfect health. It might be that if the source of infection were removed the cure would be permanent. Dr. Barac spoke of the use of 606; arsenic would certainly be an advantage, but the anemia in those cases was probably syphilitic. Bradley of Edinburgh proved that these cases in which salvarsan was beneficial were luetic anemias. An important point was that in a high degree of anemia the Wassermann was found negative. In one case in which

the Wassermann was negative autopsy showed lues from the brain down. Much pernicious anemia is luetic in origin. In one such case where they were going to transfuse a pernicious anemia patient with blood from his brother and where the patient had a negative Wassermann, and had emphatically denied lues, the donor showed a four plus Wassermann. When he was questioned he said, "Oh, yes, I got that trouble at the same time my brother did," which showed that the Wassermann reaction might be negative in these cases.

Dr. FRIEDMAN of New York said he would like to ask why these patients had remissions in pernicious anemia. If these cases originated with infections, did they have reinfections? One point he did not think was well taken. It was stated that if the infected tonsil was removed the patient would get well. This need not necessarily follow, because the damage would have been done, but that did not prove that infection did not produce the disease.

Dr. HAYTHORN of Pittsburgh said that the question that Dr. Mercur raised about the use of salvarsan in pernicious anemia should be considered. Dr. Smithies did not need support, that was evident, but he would like to say that in the last three autopsies they had had they had recovered, either from the bone marrow, the heart's blood, or the spleen, a virulent *Streptococcus pyogenes* and an unrecognized spirillum. Salvarsan in the blood stream acted as a bactericidal agent and some workers had cleared up streptococci in the blood stream by this means. Experimental animals had been saved in this way. It was not necessary for persons to have syphilis to be benefited by salvarsan. The bone marrow must be reached by the injection. He would like to see salvarsan used experimentally in cases where there was no syphilis.

Dr. IVES of New York said that they had had an extremely interesting case at the Mercy Hospital clinic that morning—an endocarditis due to *Streptococcus viridans* in the blood. In this case the injection of salvarsan cleared the blood stream of streptococci. A second injection raised the temperature, which came down in the course of a week. The third injection cleared up the case, which ran a normal temperature two or three days later. This would seem to indicate that the temperature was caused by bacteria in the blood, which were cleared up by 606. It would seem then that salvarsan had bactericidal action.

Dr. FRANK SMITHIES of Chicago, in closing, said he wished to thank the members for their interesting discussion. In his fragmentary presentation many points necessarily were left uncovered. In this disease there were definite evidences of the infective process in the mouth, as also in pellagra, kala-azar, sprue, etc. The first treatment was by a chlorate of potash mouth wash, or ½ per cent. formalin wash, before anything else was done. Many of these cases were non-luetic by laboratory tests, and it was concluded that the action of salvarsan was bacteriolytic. He was glad to hear reports from Dr. Baar of intermittently active infections in pernicious anemia. The type was a low grade septicemia by protein end-products poisoning. Salvarsan would react upon the temperature and anemia, and one could class this disease with a low grade intermittent infection such as kala-azar. He had not employed salvarsan in every case. Two patients had had salvarsan before they came. Any chronic anemia, such as anemia in cancer, could be called pernicious. The anemia was a lytic anemia, whether it was caused by bacterial or metabolic products. From a study of an immense material, Cabot had stated that 99 per cent. of patients had died within three and one-half years. The report of blood tests showed that his own patients had had all the remissions they were going to have before they came to him. Forty per cent. were brought in on stretchers; some in extremis. We did not know about spontaneous cures, but we did know that spontaneous cures had not been hindered by anything that we had done. Recurrences were not uncommon after splenectomy. The hemolymph nodes in the spine might take on the function of destroying the red blood corpuscles. Patients might come back with recurrence where there were definite alterations in the hemolymph nodes. In these cases there was disruption of the blood cells by the lymph nodes which had taken up the functions of the spleen. Dr. Friedman spoke of focal

infection. It was not sufficient to speak simply of infection about the teeth or tonsils, but it was important to say what type of infection. There might be vigorous growth of harmless organism or very slow growth of very pathogenic organisms. These could produce serious damage. Removal of the tonsil would not cure this. There might also be mutations of organisms which were harmless into those which could produce serious lesions. Rosenow had shown this. In regard to achylia gastrica, Dr. Smithies agreed that this was a constant finding in pernicious anemia, also pancreatic achylia. This state was, however, the end result, where the damage had been done. Physicians ought now to study the living pathology instead of centering their attention on dead-house pathology. If the surgeon had done nothing else, he had contributed a certain amount of pathology while the patient was still living. Posterity would laugh at us for talking of achylia gastrica and gastric atrophy which was a symptom, not a cause. Diminished hydrochloric acid or pancreatic secretion was the end result. So also with the spleen; it had suffered from a chronic, low grade inflammatory irritation, and there was no intense reaction as in typhoid fever. In ten of these spleens one might not find any organisms; in the next ten cases there would be organisms in the tissues of every one. The bone marrow cultures would tell what organisms we were dealing with in some cases. Dr. Baar's observations about indicanuria brought out the point of the chronic intermittent type of infection in these cases. It did not matter whether it was in the gall-bladder, the alimentary tract, or the appendix; so long as it was active, it would produce indicanuria. He wished further to emphasize that all one could do in analyzing these cases was to present certain facts and let men interpret them for themselves. The prophet had never been very successful so far as history went. The point he wished to leave was this: in the treatment of pernicious anemia the disease was not treated by splenectomy, but on the basis of any clinical, pathological, or bacterial focus. That taught us to reduce any infective foci, whether external, abdominal, or elsewhere; and to counteract infection by transfusion. In addition treatment might include laparotomy in the search for focal infection, and removal of the spleen if the organ required removal.

The Communicable Diseases in Modern Warfare and Their Prevention.—Dr. WILLIAM H. PARK, Director of the Research Laboratories of the New York City Board of Health, presented this communication. The writer stated that where many men were collected together in camps outbreaks of infective disease, such as pneumonia, meningitis, diphtheria, malaria, etc., might occur. In France the soldiers were protected from typhus, but the amount of tuberculosis was large. The English soldiers had preliminary physical examination in this respect, but in France many incipient cases had been found in the trenches. Trench fever was a disease that was more interesting than important. Tetanus and gas gangrene were not communicable under ordinary conditions, and the present universal use of antitoxin had largely eliminated tetanus. Typhoid and paratyphoid had been greatly reduced by prophylaxis. Outbreaks, however, did still occur of typhoid, paratyphoid, dysentery, and cerebrospinal meningitis. The latter had been prevalent among the English and Colonial troops. The civil population was not affected. The greatest incidence was in February, March, and April. In 1915 there were 3,000 cases. The investigations by the British Medical Research Authorities corroborated the findings of Dr. Bolduan of New York City in regard to carriers in this disease. The English Medical Commission insisted upon the treatment of carriers by antiseptic sprays. As in other diseases, there were many carriers, and only a small percentage of those receiving the infecting organisms became really infected. The season of the year and the susceptibility of the population were factors of importance. It was more prevalent among black than among white troops. In parts of England the disease was endemic, but not epidemic. During the past winter the percentage of cases was higher, and the carrier rate lower. This might be explained as being due to a higher virulence in the type of meningococcus. There had been increase in pneumonia, measles, and mumps. The

cold weather naturally brought the troops together in poorly ventilated and over-crowded quarters, and more infection resulted. In England four strains of the meningococcus had been isolated and these differed in immunological characters. Most cases were caused by strains No. 1 and No. 2. Observations in this country differed from those in England. Prophylactic inoculations had been tried, notably in the Texan epidemic, by Sophian, with no bad results. Several thousand men had been inoculated in the American camps. Unfortunately different strains did not immunize against each other, and type No. 1 did not immunize even against itself. In England and France various methods for handling carriers were adopted: (a) all the men were swabbed, and positive cases were removed; (b) all the men in contact with cases were swabbed—this was the method generally adopted; (c) contacts were considered as carriers; if chronic carriers were discovered and treated in summer, in winter the epidemic would be stopped; (d) disinfection of carriers by douches, sprays, and vapors. Some men, it was found, remained infected for months. Enlarged tonsils, adenopathy, etc., favored infection. The longest duration of infection was 15 months. Antiseptics used were chloramine T, 2 per cent., or zinc sulphide, 1 per cent. This increased the flow of nasal secretion. Vaporizing with these solutions was used on the transports of Australian troops, and it was found that the incidence of measles and mumps was also lessened thereby. The French used the method of swabbing the nasopharynx with carbolyzed oil. A dried antimeningococcus serum had been tried with doubtful results. As regards treatment, the serum treatment was considered of great value if the serum were potent against the type of infection. Cultures from European cases had been brought to America so that horses could be immunized against prevalent strains. The sera now obtained covered all the strains. In regard to typhoid prophylaxis, at first several thousand men died each month, but since the use of vaccine there had been only 100 cases. This was the combined result of vaccine and sanitary improvement. There were now less than 1 per cent. of cases. Dysentery returns showed that there were both bacillary and amebic types present. Amebic types were from Turkey and North Africa. Some patients had both infections. There was no specific treatment to prevent infection. Vaccines were too highly toxic to be employed. Specific serum was still in the experimental stages. In the bacillary type a polyvalent serum had been used, and the earlier the injection, the better the result. In the amebic type emetine hydrochloride was not used, as better results had been obtained by use of emetine and bismuth iodide. Pneumonia frequently occurred as the result of exposure and often followed measles. The Singalese troops were especially susceptible; they were treated by inoculation. The strains were taken from the camp cases, but the type might vary. In regard to tetanus, the injection of 500 units of antitoxin had been made compulsory in all wounds in the British Army and now less than one in 1,000 cases developed tetanus. It was given subcutaneously for fear of anaphylaxis. Trench fever was a recurrent fever affecting the English troops in Flanders. The blood organism did not strain through the porcelain filter.

THE PRESIDENT said that it seemed strange that the Army had to deal with so many cases of measles and mumps, but the country boy did not have the chance to acquire immunity against these diseases. The city street boy, on the other hand, was immune to any and every infection. The measles problem was not difficult. Plenty of fresh air and sunlight soon stopped the epidemic. Cerebrospinal meningitis cases got on well with the use of serum. In regard to typhoid and paratyphoid they had done splendidly. Sometimes the reaction to paratyphoid inoculation was considerable. If the camp water supply were absolutely safe, there would be little typhoid. Dr. Park had presented extremely comprehensive and accurate statements in a very interesting paper.

"Les Borgnes."—According to Genet one-eyed men in France numbered 1 in 1,000 before the war (age limits 23 and 42). The present ratio must be manyfold this figure.—*Annales d'Oculistique*.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, Held January 3, 1918.

THE PRESIDENT, DR. WALTER B. JAMES IN THE CHAIR.

THIS meeting consisted of a brief executive session at which the annual reports of officers and committees were presented.

Report of the President.—Dr. WALTER B. JAMES presented this report, in which he recalled that a year ago he had outlined the financial condition of the Academy and described the problem which the overcrowding of the Library had created. In May the Academy had voted to erect an addition on the adjoining lot, No. 15 West Forty-third Street, already in the possession of the Academy, and authorized the trustees and Council to proceed with this whenever they thought the state of the building trades made it seem wise to do so. Under present conditions the Council had confined itself to a consideration of plans and to the study of certain mechanical features of the project pending the time when it should be possible to go on with the building. Fortunately the same war conditions that prevented building had also limited the supply of new medical books and journals, thus helping to make the process of overcrowding in the Library less rapid. The opposition to the probate of the will of the late Dr. Witthaus had been withdrawn and the rights of the Academy as a present beneficiary and as residuary legatee were now established, and the Academy was receiving about \$4,000 a year from this source. This was a very fortunate circumstance, since it had been decided by the Fellows to permit the Council to remit wholly or in part, and in its judgment, the dues of those who were absent in the national service. The Academy might be proud of its service in the war, there being at present 200 Fellows in the service, and steps were being taken to display a suitable service flag. The Academy was coming each year to fill a more important place in the general community life, not only through the useful activities of the Public Health Committee, but through a number of stated meetings each year, at which topics of mutual interest to the profession and to the laity were taken up, and which had been well attended. The Academy had cooperated with the Corresponding Committee of the Merchants' Association in efforts to maintain a high standard of public health in the city. It was to be desired that these activities should be encouraged and extended, making this institution a more and more important factor in the city's life. The Academy's fortunate policy of complete abstention from all bias of political nature, either civic or medical, helped to make its service of greater value in all these directions. Every effort had been made to serve the nation to the fullest extent in the present national crisis. The Library had been thrown open at all hours to all men in uniform. For almost a year they had furnished without remuneration rooms for medical examination for the Medical Reserve Corps. Hossack Hall had been offered freely for public meetings for all purposes connected with the war. In spite of the fact that many distinguished and productive physicians had been called away on military duty, earnest efforts had been made to keep up the interest in the stated meetings. On the whole, the Academy had had an active and useful year and it began its new one in a satisfactory condition both financially and as regarded its physical condition and its Library.

Report of the Council.—Dr. FREDERICK T. VAN BEUREN, JR., presented this report, which showed that the Council had performed its routine duties during the year. It had transmitted to the Academy, with the approval of their adoption, amendments to Article III, Section 1, of the Constitution and Article X, Section 12, of the By-Laws, which were adopted by the Academy at the stated meeting, held December 6. The first of these amendments was as follows: "The number of Fellows residing in the City of New York and paying dues shall be limited to thirteen hundred, and the number not residing in the city nad paying dues to two hundred and fifty." The second: "It shall be empowered during the continuance of the war to remit, wholly or in part, or permit the postponement of the payment of the dues of any Fellow while in active service, or to transfer Fellows in such service from resident to nonresident membership." This report urged that the several annual re-

ports which had been presented to the Council and published should receive the attention of every Fellow of the Academy.

Report of Trustees.—Dr. CHARLES L. DANA, chairman, and Dr. NATHAN E. BRILL, Secretary, presented this report, which stated that the Board of Trustees of the New York Academy of Medicine had attended to duties in the matter of invested funds, the personal property, and the real estate of the Academy, and all business that had come before it. The report dealt mainly with the financial affairs of the Academy.

Report of Committee on Admission.—Dr. JOHN DOUGLAS submitted this report, which showed that the Committee had recommended sixty-two men for election to Fellowship.

Report of Committee on Library.—Dr. HAVEN EMERSON presented this report, which called the special attention of the trustees, Council, and members of the Academy to three important matters. These were as follows: (1) There had been a marked reduction in the number of readers consulting the Library during the past year. This was due to the absence of large numbers of the members upon war duty. Readers of the nonmember class having access to the Academy up to 2 o'clock daily were as numerous as before. (2) Fewer books had been acquired and circulated, due quite evidently to the diminished production of important medical works, both here and abroad, since the beginning of the war. It was, however, to be especially noted that pamphlets, reprints, and monographs had been circulated in a constantly increasing number. (3) The overcrowding of the stockroom and of all available space had reached such an extent as to cause great anxiety lest permanent disorder and disorganization of service should result. The Library Committee unanimously appealed to the Trustees to push the project of new space and facilities for the Library with all possible speed. The Library fund had received from the First District Dental Society \$100 for the purchase of books and journals on dentistry, which enabled the Library to make valuable accessions to its dental literature. The Academy had received from its Museum a number of interesting gifts, namely, from Dr. A. B. Jamison, an army medical chest found on the battlefield of Bull Run; from Dr. Joseph A. Andrews, five hollow-eye specula for irrigating the conjunctival cul de sac; from Dr. Howard Lilienthal, an antique clinical thermometer, and from Dr. Fanueil S. Weiss, a scalpel used by Dr. D. W. Bliss, Surgeon-General, in the operation upon President Garfield in 1881. The total number of books in the Library on December 12, 1917, not including duplicates, was 108,652, which was 3,136 more than on December 11, 1916. The number of readers using the reading room had increased steadily year by year. In 1908, 16,422 readers were registered, and in 1917, 24,750, including holiday and Sunday readers.

Report of Statistical Secretary.—Dr. ARTHUR M. JACOBUS submitted this report, which showed that the Academy had lost twenty-two Fellows by death during the past year.

Treasurer's Report.—Dr. REGINALD H. SAYRE presented this report, which showed that the finances of the Academy were in a very satisfactory condition.

These reports were all adopted and placed on file.

An amendment to the Constitution and By-Laws of the Academy was adopted providing that the name of the office of Statistical Secretary be changed to Historical Secretary. The duties of the office, however, remain practically the same.

Revival of the Cuirass in the Present War.—Delorme suggests that it would be well to introduce the use of a steel breast plate among the troops exposed to rifle and shell fire. The helmet has rendered good service to the cranium and a breast plate long enough to protect both chest and abdomen might be the means of saving much life from central wounds. The old fashioned buckler went into disuse with the introduction of the musket. While something might be done today with an improved shield a cuirass would answer well against shell fragments which do not possess the penetrating power of rifle bullets. Central wounds of the lung have a high death rate and some effort should be made to protect the troops.—*Le Progrès Médical*.

Therapeutic Hints.

Chlorine Water in the Treatment of Infantile Diarrhea.—S. Roseberry advocates the use of chlorine water in the following mixture:

℞ Aquæ chlori ℥ iv
Quininæ sulphatis gr. 1/8
Salol gr. iv
Mucilag. tragacanth ad 5j

M. et Sig.—3ss. to a child under six months, and proportionate doses in older children.

The above mixture is given every six hours for the first twenty-four to thirty-six hours, and then three times a day until the stools are normal. In addition, the following mixture is administered twice a day:

℞ Ol. ricini 3j
Ol. olivæ 3j
Tinct. opii ℥ ij

M. et Sig.—Ten to 20 minims, according to age, twice a day.

The opium, however small the dose, has a soothing effect upon the bowels, and helps to induce a much-needed rest, which is an important factor in treatment. Lavage of the bowel with saline solution is also beneficial.

In the very severe, collapsed cases, a mustard bath may first be given, followed immediately by injection of pituitrin 1/6 c.c., repeated two or three times at intervals of four hours. Then an inunction of warm olive oil may also be given to diminish loss of heat from the skin. Lavage of the bowel may be done two hours after the mustard bath. The diet in these cases varies according to the severity of the attack. In the milder cases albumin water and barley water are sufficient. In the more severe cases sherry whey may be given until the vomiting ceases.

The majority of cases recover in four or five days, the more severe in from ten to twelve days. In the latter it is often necessary to administer brandy in 10 to 20-minim doses every two hours, as an additional check to collapse, and in such cases Roseberry has found that thyroid, gr. 1/6 twice a day, is useful in helping to accelerate recovery and increase weight.

As the cases improve and just before discharge from hospital, they are placed on some one infantile proprietary food suitable to their digestion.—*British Medical Journal*.

Treatment of Itching with Hemorrhoids.—Hare suggests the following formula for relief of itching with the presence of hemorrhoids:

℞ Mentholis gr. xx
Hydrargyri chloridi mitis gr. xxx
Petrolati 5j (30)

M. et Sig.—Apply locally.—*Practical Therapeutics*.

Incontinence of Urine.—Where the urine is acid, concentrated, and dark in color the following formula is especially beneficial in these cases in children.

℞ Potassi citratis 5ij (8.0)
Spiritus etheris nitrosi f5ij (8.0)
Aquæ destillatæ ... q.s. ad f3iij (90.0)

M. et Sig.—Dessertspoonful (8.0) every four hours in a tablespoonful (15.0) of water.—Hare in *Practical Therapeutics*.

THE PROBLEMS OF DRUG ADDICTION.*

By CHARLES L. DANA, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE.

THE opium and its alkaloids imported yearly from 1912 to 1915 amounted to about 2 billion doses, or an equivalent of 2 billion grains of opium, or $\frac{1}{2}$ billion grains of morphine. This is about 20 grains of opium per capita or 100 grains per male adult yearly.—(Bulletin U. S. Public Health Service.) It is estimated by M. I. Wilbert of the U. S. P. H. S. that there are about 175,000 addicts in the United States, or about 1 to 600, and on this basis there are 15,000 to 20,000 in New York State. The number no doubt fluctuates and has perhaps been lessened by the enactment of laws and the reduction in the amount of the drug imported, and its increased cost. In 1915 the amount of opium and its alkaloids imported was less than in 1913 by 531,-840,000 grains. Whether this is made up by illicit importations is not known.

The following table was prepared and kindly furnished to me by Dr. George R. Kirby, director of the Psychiatric Institute at the Manhattan State Hospital.

*Read at a meeting of the New York Psychiatric Society, Jan. 3, 1918.

Bearing on the question of the prevalence of drug addiction, I would quote the statement of Justice Collins of the Court of Special Sessions of this city, who says that 10 per cent. of all cases coming before the Court of Special Sessions are drug addicts.

The question arises, first, whether these 15,000 addicts in New York State, for example, are enough of a menace to warrant taking severe measures to prevent the results of opium addiction. Most addicts are constitutionally unstable persons, likely to be a burden or a menace to society anyway.

Drug addiction does not lead to insanity or the serious psychoses needing custodial care. The percentage of such cases in State hospitals is very small. It is very large, however, in prisons and reformatories, and it would seem as if drug addiction had more relations to crime and social waste than to psychiatry.

The drug addict is not usually a mental defective, and a series of intelligence tests would not disclose a large percentage of morons and imbeciles, as happens in certain other anti-social groups.

But on the whole there is no doubt that drug addiction makes the normal and abnormal man more dangerous to society. It intensifies his possibilities of harm, though on the other hand it shortens his career. There is reason enough to justify serious effort to lessen the social dangers and personal misery from this source.

The problem of control and amelioration is twofold: first, the prevention of drug addiction; second, the relief and care of those affected by it.

In drug addiction there is a morbid condition of metabolism which arouses a very uncontrollable need for opium. This may be called a disease, or not, according to one's fancy in the use of words. It may be there is a functional defect or perversion of the endocrine and vegetative nervous system. Drug addiction is a vice, or moral or mental defect, in the sense that the condition is often deliberately or stupidly acquired and persisted in.

With regard to the relief and care of this condition nearly all are agreed:

1. That there is no specific cure. There is, indeed, not even any specific method of relieving the patient temporarily. This is easily and safely done by simple institutional methods. And this may be called specific, if you choose.

2. There is no method of securing permanent cure of established addiction except that, at times, by long and expensive institutional and personal treatment, including methods of physical and moral reeducation, success results.

It is not, however, economically wise at the present time for the State to undertake the cure of this

class. Assuming that we have in New York State 15,000 addicts, the expense of their care and cure for a year would be not far from \$300 to \$500 each, or a total of from \$4,000,000 to \$7,000,000 yearly. City and State efforts in this direction should be postponed until the method and means are better established. The establishment of psychopathic hospitals and wards throughout the State would help to this end.

The question is raised whether the State should not provide for the addict, since it deprives him of his drug without making any provision for his consequent suffering. To this I would say that the State ought to furnish means of removing the drug and of educational treatment at this time, and a short period of care during recuperation. This is done in the large cities, and it ought to be a function provided for in country districts.

It would be best to treat what addicts we now have symptomatically, and try to prevent the development of new cases. This is being done at present by means of legislation controlling the output and use of opium. For this we have so far, in New York State, the Federal or Harrison Law, and the Whitney or State Law.

The Harrison Law simply provides that all persons engaged in the production and manufacture of opium, coca leaves, or any compound or preparation derived from these two, shall register with the collector of internal revenue of the district their names, places of business, the amounts imported, manufactured, and sold, and pay a special tax at the rate of one dollar per annum. The Federal Government has no police power, and therefore the law is simply in the form of an excise tax law, its aim being to ascertain the amount of manufacture and sale of the drugs.

The Whitney law is more elaborate, and has received a great deal of criticism. (1) The doctors claim that it puts a great burden on them and does not do any good. (2) Under this law the addict can be prescribed for by doctors, and he thus gets his drug more cheaply and easily than if he depended on the foreign mail and on the peddlers. I do not, however, undertake to discuss the law at this time.

Finally, I have limited my discussion to the use of opium and its derivatives. There is no need of legislating about cocaine or chloral, or the sleep-producing drugs as yet. The cocaine habit alone is rarely seen, and is curable. Chloral and veronal addiction are relatively rare, and not, usually, difficult to control.

What seems most indicated is a federal law that will make the methods of control uniform throughout the country.

One simple and efficient measure would be a federal law abolishing the manufacture of heroin altogether. These are the two courses which I would recommend.

Furthermore, it is well established that addicts cannot be treated effectively except in institutions or in institutionalized homes. Possibly a law compelling the treatment of addicts only under institutional conditions and only by specially authorized physicians might well be passed. But at present the State is not equipped in rural districts to enact such measures.

The New York Psychiatric Society has already recommended that in every city of the first class, or county or congressional district, there be established a psychopathic ward or hospital. One of the functions of these places might be to take care of addicts.

Summary and Conclusions.—The following summary and conclusions represent the results in part of several discussions and of conferences with a committee of the New York Psychiatric Society and with the executive committee of the Public Health Committee of the New York Academy of Medicine.

I do not put these conclusions down as representing their views, however, but only as containing results of criticism and suggestion from these sources.

1. It is estimated that there are about 15,000 to 20,000 addicts in New York State. They present a serious social menace, contributing more to crime and dependency than to insanity.

2. The cure of established drug addiction is difficult, long, and expensive. It is doubtful if the State should undertake the task with its present equipment. Later, with the establishment of psychopathic hospitals, it may be considered.

3. It is doubtful whether it will be wise for New York City to use its farm at Warwick for this purpose. Addicts do not do as well in farm colonies as alcoholics.

4. Drug addiction is not to be regarded as a special disease, and there is no specific remedy or cure for drug habits. There is no especially effective drug measure for ridding the patient of his drug. This is done most effectively in an institutional or hospital ward, treating the patients under restraint, and using simply, or mainly, a gradual reduction, with attention to food and elimination.

5. Addicts should be treated only in institutions or under institutional conditions. Reeducational methods should be applied at this time, and the patient should be kept long enough in the ward or in a convalescent institution to become reestablished in health.

6. The present group of chronic addicts can only be treated symptomatically, given withdrawal treatments when desired or required, as indicated above in No. 4. The State owes this to the patients whom it deprives of their drug.

7. Present efforts should be especially directed (a) to abolishing the manufacture of heroin altogether, and (b) to securing the enactment of a Federal law which will control the distribution of opium and its derivatives from the factory to the patient.

8. There is no need at present of stringent laws against the distribution of cocaine or of chloral and other sleep-producing drugs.

9. The creation of an establishment for scientific research in order to find a "cure" for drug addiction is not wise until the control of opium distribution has been secured; and then it will not be necessary.

10. In the writer's opinion, the causes of drug addiction are very well known, in so far as such causes have bearing on methods of prevention and care of these cases.

INITIAL WORLD WAR MATERIAL AT THE ARMY MEDICAL MUSEUM.

BY R. W. SHUFELDT, M. D.

WASHINGTON, D. C.

MAJOR, MEDICAL CORPS, U. S. ARMY,

As the present great war drags wearily along, it seems to become more and more problematical as to when the world will see its end. It is now far into its third year, and this country has but just declared war upon Austro-Hungary—Germany's chief ally. One by one—often several months apart—the South American countries either break off relations with Germany, or else, as Brazil did, actually declare war upon her. China is not fully awake yet, and Japan is reserving her power for eventualities. The United States cannot possibly come into it with her maximum weight and strength for fully six months more or even longer; as for Russia, not a soul living has the faintest idea what may happen next, nor when it does happen what the effect will be.

Even as early in the conflict as this, some of this

FIG. 1.—Helmet of British soldier (4239, Misc. Series). Donated by Major Wm. Lyster, Med. Corps, U. S. A.

war's profound and far-reaching effects are quite patent to ordinary thinkers and observers—ere long the more subtle effects will be equally apparent. In the case of those nations under its influence, great changes are already to be noted in the mental attitudes of people; and these, in time, are certain to produce more or less permanent psychological characteristics, which will vary in accordance with racial differences and individual temperaments, as either may be affected by environment changes. So, too, as the general unrest persists, the unabated slaughter continues, and the end seems far off, the activities of man will, in turn and in due course, be powerfully affected.

Here, in the United States for example, there is not the work of a single trade or profession that will not, in one way or another, be influenced by the general reaction. Already the literature of the country, of nearly every description, is intensely impregnated with what has been popularly designated as "war flavor"; all the gentler pursuits of our people

have, to a large degree, been affected in a similar way, while in some instances they have been suspended almost entirely.

Our output of the literature of science in some departments—never very large at the best in pro-

FIG. 2.—French military cap, with its metal lining (detached). Perforations from bullets and shell-fire (4542, Misc. Series). Received from Director Jacobs, Sanitary Service, Val-de-Grace.

portion to the country's wealth and population—has, within the last two years, been practically set aside; and, should the suspension be long con-

FIG. 3.—French steel helmet (Misc. Series, 4536)

tinued, its awakening in the future, when the war flame ceases to burn (not, let us hope, for the lack of material to consume), will be no easy task for science to accomplish. In fact, from the White House to the occupant of the very last cradle in

the land, the country is throwing its energy and resources into the present conflict, with the purpose to win it so set that no power known to man can now prevent it. We have every reason to be proud of this awakening and this putting-forth of our

FIG. 4.—Gas mask (German). From Director Jacobs (4516).

strength; but, with it all, there are matters of the most vital import to the country at large, which, in the turmoil of war and results of war, must not be lost sight of for a moment under any consideration. In large part, the present article will be devoted to inviting attention to one of the governmental enterprises that has received but scant aid for many years past; indeed, the assistance has been of such slender proportions financially, that it has brought the institution almost to a standstill, and practically to the very verge of impoverishment—in comparison with what should be accomplished in its legitimate sphere of usefulness. Reference is made to the Museum division of the Library and Museum of the Surgeon General's Office in Washington; and, in thus once more inviting attention to this matter, physicians and surgeons, and all specialists connected with those professions, are the ones especially invited to heed what is here set forth in the following paragraphs.

The great body of the world's physicians and surgeons to-day are the descendants of those who lived, fought, and carried on the labors of the profession during the years that the Civil War in the United States lasted and closed. It is surely unnecessary to point out to those of us who represent the present-day body of the latter the benefits that flowed from the foresight of the surgeons of the Federal Armies during that war and for many years thereafter. It filled a museum with material of every description,

exemplifying military medicine in all its branches, the utilization of which by the profession has largely contributed to the establishment of the place we now occupy in the world's estimation for efficiency in what the profession demands in practice. It is quite unnecessary to dilate upon the facts—its vast importance and far-reaching beneficial influences being now a matter of history and fully appreciated.

It has already been pointed out in the *MEDICAL RECORD* (October 20, 1917) that this museum, of the Library and Museum of the Surgeon General's Office, many years ago practically came to a standstill. It filled up; and the lack of space for specimens, coupled with the abrogation of proper Federal support in times of profound peace, in due course made a mummy out of the dead one it came in time to be. This mummy gave rise to an atmosphere of stagnation in its sarcophagus that by no means encouraged investigation. Still, through the strenuous efforts of the Museum's officers on duty there at various periods—especially those on duty there at the present time—the aims and the growth of the institution have not been entirely extinguished; it retains the essential life-spark, making revivification possible, and its usefulness once more a possibility.

The time is at hand when the material which the present armed struggle—the world-wide battle

FIG. 5.—Antigas mask (Misc. Series, 44f9).

being fought to burn the yoke of military domination—will necessarily place at our disposal, must be properly conserved and made available for the use of medical men in the years to come. We, the military surgeons of the United States, will pri-

marily deserve the imprecations of all those of the profession that follow us, if we fail to induce the Government to erect the structure that has been planned to take the place of the present building, dedicated long ago to such purposes, and fail to

FIG. 6.—Bulgarian sword bayonet (4232, Misc. Series).

stock the new cases of that building with the material sent in from the several battle-fronts and elsewhere, and with every possible and desirable class of specimens illustrating military medicine and surgery in all of their departments.

Among much else, this material should present everything of value furnished through post mortems; through operations in the field and base hospitals; missiles and weapons of every possible description—the latter before use, and the former when taken from wounds or elsewhere; dressings, gas-masks; means employed for bodily protection; stretchers and other means for the transportation of the wounded; Red Cross materials; tentage for operations on the field; surgical instruments; casts of results of surgical operations—in short, anything and everything tending to illustrate fully the operations, status, material, and results obtained by mili-

tary surgeons and physicians of all nations during the present war, and as long thereafter until the exhibit and its published history is absolutely complete in every possible detail.

As pointed out, the war has now been going on for over two years, and this country entered it many months ago. It is therefore a fair question to ask: what has the United States thus far accomplished to the end that a complete exhibit and history of military medicine of the present be prepared and passed along to our successors, to be utilized by them in years to come, long after this terrible conflict has become past history?

In so far as the Army Medical Museum is concerned—very little. That is not due, however, to any lack of demonstrating the necessity for such endeavors by the Department and its officers; through such channels this has been made clear over and over again. Steps have been taken at the front to send to the Museum everything enumerated above—and more, if possible. Medical officers at the various seats of war in Europe have been instruct-

FIG. 7.—Upper figure: German hand-grenade. Director Jacobs, donor. Lower figure: Russian cartridges. Donated by Major J. H. Ford, Med. Corps, U. S. Army.

ed to attend ceaselessly to such matters. If stimulated through further orders and requests, it is very probable that, when our armies become more extensively engaged, the material described will begin to flow in, as it did during the latter years of

our Civil War. When that happens, the new Army Medical Museum should be ready to receive the contributions.

At the present writing, there is at least one case in the Army Medical Museum which has been set aside for the reception of such material as either has been or may be forwarded by army surgeons serving with our troops at the front. This case is about half filled, the specimens having all been fully and carefully labeled by their custodian, Dr. D. S. Lamb, of the Museum's staff. Doctor Lamb also has in his keeping such histories as have been sent him of these specimens; they have been card-catalogued, and these facilities have, through him, greatly assisted in the production of the present article.

by swords and bayonets. There are a couple of British helmets of the form shown in Figure 1, with a few bayonets and knives picked up on the battlefield. The collection of canteens is very interesting, some of them being very crude and unhandy, especially the Cossack type, of which there is one specimen made of wood and having the form of a little flattened barrel. The metal work on it is far inferior to that turned out by our American Indians. There is a small collection of missiles of various kinds, including scraps of shrapnel, shells, grenades, and so on.

Another small collection represents French and German first-aid equipment, and a German antitetanus serum outfit, found at the aid-station of Cav-

FIG. 8.—Various missiles, shrapnel balls and bullets, cut from wounded soldiers at the front. Director Jacobs, donator. Natural size.

In this collection we find a series of types of various styles of gas-masks, in use by officers and men of the armies of the different nations; also the receptacles to hold them when not in use. Old and new styles are both represented, also some elaborate apparatuses for the resuscitation of those overcome by gas. One or two foreign stretchers are in evidence; also a sling for carrying sick and wounded (No. 4,271), contributed by Mrs. Mabel Van Vechten, of New York. There are nearly a dozen helmets that belonged to French soldiers killed in battle; they are all of the type shown in Figure 3, and generally present evidence of the penetrating missile that killed the wearer; also of mutilations

erne du Dragon (July, 1917). There are other small collections of familiar material, including first-aid material. Finally, we have a series of relics of no especial importance, in so far as military medicine *per se* is concerned; they belong more properly to the National Museum. We have in this series the insignia of the British Red Cross Society; a shoe that belonged to the horse of a Russian officer; many objects taken from the pockets (and elsewhere) of the dead on the fields of battle, as pocket knives, finger rings made from pieces of shrapnel (Russian), belt buckles, crosses, etc. Objects of this class should be relegated to the exchange series, as they are not of sufficient value from the standpoint

of the surgeon to warrant the space they occupy.

There are a number of other specimens of greater or less value; but these need not be enumerated here, as they are illustrated by means of the cuts in the present article—the preparation of which would have been quite beyond the pale of possibility had it not been for the cordial assistance and co-operation of the officers and others attached to the Museum, in whose power it lay to render assistance. For this, and more, sincere thanks are extended to Col. W. O. Owen, Medical Corps, U. S. Army, in charge of the Museum, for issuing a general order to those in his command to extend to me every facility needed for the completion of the work in hand. For special suggestions with respect to the material to be selected, and for marked encouragement in the work, the writer is much indebted to Col. Champe Carter McCulloch, Jr., Medical Corps, U. S. Army, in charge of the Library of the Museum, and to Col. Louis A. La Garde, Medical Corps, U. S. Army, also connected with the Museum, and author of the standard work on "Gun-shot Injuries." Col. La Garde kindly examined the illustrations and specimens of bullets and other missiles, and gave much important information in regard to them. Mr. Cary R. Sage, of the Library, rendered most valuable assistance and encouragement in matters having to do with the photographic department, correspondence, and consultation of authorities. It affords the author especial pleasure to extend his thanks for the assistance of this most efficient member of the personnel of the Library, in which he is chief assistant.

Finally, it was most fortunate that the photography of the material reproduced as cuts to illustrate this contribution fell to Mr. Roy M. Reeve, who has charge of the photographic department of the Museum. The original negatives used are six and a half by eight and a half, made by the use of the photostat camera. The prints from them speak for themselves, as well as for the skill of the artist who made them. In regard to the photographs, it may be said that we have in Figure 1 the heavy metal helmet of a British soldier killed in battle. The exit of the ball is plainly to be seen, the missile having struck him in the face and passed directly through.

Figure 2 is a French military cap with its metal lining detached and placed below; the latter has two soft linings (not shown here). This man evidently received two fatal wounds simultaneously, both being perforating ones. A piece of shell or shrapnel hit him from below, passing through the metal lining and the cap, while a small missile entered just below it on the cap, and passed clear through. Either shot would have been fatal.

Many French soldiers wear helmets of the pattern shown in Figure 3; it is of thin metal, with a chin-strap. The one here shown was worn by a man who was shot through the head, the small bullet-hole being just to the left of the insignia in front. Before receiving this wound, he had evidently been struck on the head a glance blow with some other weapon, scarring the metal as shown.

Gas-masks are of an infinite variety of models. The one shown in Figure 4 is German, and not now used. It was found near Cielu (?) in the Somme, August, 1916. Another type is shown in Figure 5—a style made in various patterns. It is made en-

tirely of some flexible, transparent material, and is very light. There are several ways of carrying the gas-masks. Some of the earlier ones were clumsy affairs, unhandy to use.

The bayonet used by the Bulgarians is a small one and an old-fashioned model. It has a length of about 20 cm., the actual blade being but 15 cm. Doubtless it can readily inflict a fatal wound, while its small size and easy attachment to the piece render it an easy one for the soldier to carry and use; when detached, it may be used as a big dagger.

Not many models of hand-grenades have come in as yet—a deficiency that may be met later on in the war. An ingenious one, however, is here shown in the upper illustration of Figure 7. It is a German device, and is known as the "turtle type." It is a hollow iron sphere, nearly 8 cm. in diameter. It is grooved and weakened as shown, and doubtless, when it explodes, the various pieces are thrown violently about, doing as much damage as the balls from a shrapnel. The form of the handle, and the manner of igniting the explosive, were apparently not sent by the contributor.

Below this hand-grenade there is a Russian cartridge carrier, containing five cupro-nickel, steel-jacketed bullets in fixed ammunition shells of brass. This is a most effective ball, possessing marked power of penetration and high velocity.

There are some interesting missiles presented in Figure 8, selected from a large number of others; the ones here shown were extracted from wounds by operating surgeons. Most of them are deformed through having hit some other object, either metal or otherwise, before striking the officer or man. Those marked *a*, *e*, *g*, *h*, *i*, *j* and *n* may be exceptions.

a—*f* are French bullets ("slug of bronze"), model D, deformed by use. From the Champagne front, 1915-16, *g* is a piece of shrapnel-casing from elbow-joint, and *k* is the brass from around the casing; it was removed from the same wound (Austrian, 1915). In *h*—*j* we have three shrapnel balls of cast iron; they are of the type used by the Austrians.

l, *m* and *o* are deformed Austrian bullets, *l* having mushroomed before hitting the man; *m* is a jacketed bullet, which also struck some hard object before ricochetting and killing or wounding a soldier. *o* is a ball like *l*, and probably penetrated a man without having hit anything first. *n* is a Mauser bullet from the same collection, with no special history. In the first series, *e* looks very much like a ball that had been distorted through having come in contact with some of the denser structures of the body, not having struck anything previous to penetrating a man. Firm muscular tissue or a dense tendon will deform a ball of this kind when shot into it at a medium velocity.

3356 EIGHTEENTH STREET.

Psychic Factor in Postchloroform Vomiting and in Vomiting After Gastroenterostomy.—The association of psychic and somatic factors in the genesis of obstinate vomiting is well known, and the late Dr. Mathieu, prominent as a gastroenterologist, was able to isolate a psychic component, even in the vomiting which follows chloroform anesthesia (the subject seems obsessed with the notion that the chloroform must be gotten rid of). A similar motivation is seen after gastroenterostomy.—*Soc. Méd. des Hôpitaux.*

VENEREAL DISEASES; THEIR RELATIONS TO INSANITY AND NERVOUS DISEASES.*

By JOHN JOSEPH KINDRED, M.D.,

RIVER CREST, ASTORIA, L. I., N. Y.

CONSULTING PHYSICIAN, RIVER CREST SANITARIUM AND THE BELLE MEAD FARM COLONY SANATORIUM.

THE occasion of this paper is emphasized by the fact that the present annual meeting of the society, at the request of the Federal health authorities of the U. S. Army and Navy, is to discuss as the chief topic the general subject of the control and effects of the sources of infections as they are related to the newly drafted army.

The relations of the two chief classifications of venereal diseases, namely, syphilis and gonorrhea, to insanity and nervous diseases, are important and are here considered from their etiological, sociological, and economic viewpoints. Syphilis is the chief causative factor in that dreaded form of insanity known as paresis, a fatal disease divided, in typical cases, into three stages, characterized by classical symptoms and extending over an average duration period in all cases of about five years. Most authorities hold that syphilis is such a constant etiological factor in this disease that even without the presence of a Wassermann reaction every case of paresis is considered by them as having had syphilis prior to the development of paresis. All authorities regard a combination of sexual and alcoholic excesses and worry as the causes of paresis and even if, in a given case of this disease, we can get no positive history of syphilis, we know that it could be assumed to exist in paretics, who present the usual history as to etiology. Hospital and private practice brings the alienist in contact with a large number of syphilitic and parasyphilitic mental diseases, characterized by syphilitic brain and cord changes, and also meningo-encephalic cases, many of which resemble paresis. Syphilis also plays a part, as a complication, in the causation of some of the other psychoses, like manic-depressive insanities, and mental conditions of stupor and loss of memory as well as some of the mental states marked by moral lapses, loss of self-control, etc.

The syphilitic origin and gummatous nature of many cases of brain tumor, with and without mental symptoms, amounting to insanity or feeble-mindedness, is pointed out by the Wassermann reaction tests. Other cases of syphilitic origin develop more or less rapidly or slowly, often in the form of apoplexies, aphasias, anesthetics, hyperesthesias, paresthesias, hemiplegias, monoplegias, and irregular paralyses, in many cases the cord lesions ascending and finally involving the brain. In some of these conditions there are accompanying disturbances of the reflexes, loss of sexual power, paralysis of the bladder and bowels, tabes, neuritis, and trophic disturbances. Some of these present as their chief clinical mental symptoms mild egotism with a paranoid trend. These cases may have a duration of several years. Many epilepsies (not typical grand mal) and epileptoid

conditions, with or without mental impairment, are of syphilitic origin.

The serious effects of syphilis on the brain and cord and the consequent impairment of the mind and normal functioning of the nervous system, occur in the tertiary stage of syphilis, with the possible exception of a few rare forms of primary syphilitic disease of the nerves.

Syphilis was the cause of 18 per cent. of all the insanity in men and about 13 per cent. in women, in 5700 first admissions, the total number of admissions of insane cases to the New York State hospitals for the insane within a recent year. In other words, of 5700 insane men and women admitted during the year, 18 per cent. were men suffering with paresis caused by or associated with syphilis and about 13 per cent. were women paretics or parasyphilitics, whose condition was due to or closely associated with syphilis.

Notwithstanding this significant showing as to syphilis in its etiological relations to insanity, only about 5 per cent. of all syphilitics develop outright insanity. This would seem to prove that the cerebrospinal system in this 5 per cent. is peculiarly susceptible to the syphilitic poison, particularly in those who have not been given to alcoholic and sexual excesses and undue mental worry and anxiety. In most cases of paresis, however, we have both susceptibility and a history of excesses. The fact that such a small percentage of syphilitics develop insanity, when we consider the mischievous effect of syphilis on so many of the bodily organs and tissues, leads us to the conclusion that syphilis after all, in many cases, may be considered to this extent a somewhat benign disease, especially if thoroughly and systematically treated from its incipency by modern methods. While some of the roseate hopes for uniformly successful results of the salvarsan and neosalvarsan methods and other modern methods of treatment of tertiary syphilis, unfortunately, have been shattered, yet it can be conservatively claimed and proven that the modern treatment of tertiary, brain, and spinal syphilis has in many cases been positively brilliant.

In connection with non-susceptibility, it is an interesting fact that the full-blooded members of the yellow, brown, and black races are relatively immune to syphilis of the nervous system. They escape in much larger proportion than the white race despite their utter neglect of treatment and hygiene.

The effect of syphilis in causing and complicating nervous diseases, as distinguished from the psychoses, is so far reaching that it may be truly said that in every one who has had syphilis this disease has to be considered as possibly being, directly or indirectly, associated with all nervous diseases, and indeed many other diseases that may be developed by these persons. This, of course, suggests that frequent Wassermann and other tests should be made in these cases and that antisymphilitic treatment should be administered accordingly.

Syphilis also plays an important part in the causation of the large class of so-called neurasthenics, who are usually classified as nervous rather than as mental cases. I here classify neurasthenia as a nervous disease because it does

*Presidential Address, read at the annual meeting of the Queens-Nassau County Medical Society, November 27, 1917.

not belong in its ordinary manifestations to any of the classifications of the pure psychoses. It is really in most of its forms a neurosis (associated by some authors with "anxiety neurosis") or a psychoneurosis, with visceral symptoms and hypochondria.

Of 2500 cases of syphilitics collected in the practice of one of the leading American syphilographers, 504 (25 per cent.) were afflicted with syphilis of the nervous system; of all of his patients noted showing tertiary and parasyphilitic lesions 42 per cent. showed disorder of the nervous system, including the common ocular and aural complications; among this number 113 had more or less serious tabes; of the remaining number about one-fifth were permanently and gravely disabled by nervous disease. It is admitted beyond question that locomotor ataxia is a parasyphilitic disease. It has already been pointed out that many of the syphilitic lesions of the cord ascend more or less rapidly to the brain, causing paresis and parasyphilitic insanities. Syphilis of the nerves and nervous system, as has already been stated, is not primary but depends upon the involvement of the syphilitic disease of the cells or tissues of the brain, cord, and meninges or of the surrounding bony or soft tissues.

Gonorrhea plays an important rôle in the causation of many diseases in both sexes. Severe and stubborn infections, like certain forms of rheumatism, etc., often follow gonorrhea. These infections and direct complications of gonorrhea have important bearings. The old current statement perhaps not much modified at the present day, that some 60 to 80 per cent. of young unmarried men and a certain percentage of married men suffer at one time or another from gonorrhea, is significant etiologically, sociologically, and economically. This significance is emphasized by the fact that gynecologists agree that from 60 to 80 per cent. of pelvic suppurations in women requiring hysterectomy or oophorectomy, are due to gonorrheal infections.

The direct effect on society of gonorrhea is obvious, both as a predisposing cause of mental and nervous diseases as well as a sociologic and economic factor. Not only are many married women of a high normal, mentally and morally, prevented through this infection, through no fault of their own, from bearing fine children, but because of illness their industrial producing capacity is either entirely or partially destroyed.

Office records, extending over half a century, quoted by a leading American authority, indicate that the proportion of syphilitics to gonorrheics in New York City, among the upper and middle classes, is from 1 to 8 to 1 to 15.

Some idea of the loss of efficiency in the United States Army and relatively also in the civilian population of this country, can be gained by reading the report of the surgeon general of the army for the year 1904. This report reads in part:

"By far the most important diseases affecting the efficiency of the army during the year have been the venereal . . . causing 16 per cent. of all hospital admissions, 28 per cent. of all non-effectiveness, and 18 per cent. of all discharges for diseases." A distinguished specialist analyzing

the surgeon general's report, truly says that the figures and facts stated therein mark syphilis as one of the great scourges of the human race, and observes that more soldiers are rendered permanently unfit to follow their profession by syphilis than by any other disease.

No class is spared by syphilis or gonorrhea. While syphilis may not strike those of wealth and social position as hard as it does the poor and lowly, it is no respecter of persons or classes in its startling prevalence and terrible effects.

AUTOINTOXICATION — AN ETIOLOGICAL FACTOR OF NEUROSES OF CHILDREN.*

BY WILLIAM R. WOODBURY, M.D.

ROCHESTER, NEW YORK.

METCHNIKOFF's theory has done two things: It has given a means of combating autointoxication; and it has revealed the far-reaching and remote effects due to this condition. Nutrition is constructive. Malnutrition is destructive. The three factors in nutrition are the mouth, stomach, and intestines. These three factors working orderly maintain nutrition; working disorderly they do not maintain nutrition. With malnutrition disease is always within striking distance. These are fundamental facts upon which hang the whole movement of growth and development of children. They are facts of first importance, and are responsible for far-reaching results.

Malnutrition is the first cause of every form of sickness. A stealthy and subtle foe, always alertly ready immediately the chance comes to take full advantage, malnutrition strikes its blow, and grips its victim. Once it gets a hold it is a giant task to defeat it. Like a strong, rank weed, it pushes its far-flung roots throughout the entire body, sapping life and spreading disease. Malnutrition retards growth; it causes all the physical defects of childhood; it opens a way—and keeps it open—for all the infectious diseases; it lays the foundation for general body diseases; and it is the first step toward a weakening of the nervous system, a weakening which gives foothold to the conditions which develop into disturbances of nerve balance, and nerve disorders and diseases. The nerve disorders which are known as functional have their source in malnutrition.

There are certain important facts about childhood which often are not learned until it is too late. The mother is not told them. Physicians generally pass them over as being of no practical importance. In the interest of the child there is urgent need that mothers should know all about the teeth, and what a clean, whole mouth means. She should know when to look for the coming of every tooth; how to take painstaking care of these necessary organs of nutrition; and, particularly, how to prevent decay so that not a single tooth shall be lost before its full work is done. The importance of this, the first cause of malnutrition, and the big fact that it continues to work as an increasing damage as more and more the teeth begin to rot, and become worse than useless—these facts need to be strongly em-

*Read at the Tenth Congress of the American School Hygiene Association, at Albany, N. Y., June 7, 1917.

phasized. Close knowledge of how the teeth—the child's chewing tools—develop is needed. Their importance as organs of digestion and nutrition is told by the fact that at the time of birth the child has all its milk teeth and some of its permanent teeth compactly stowed away in its little jaws awaiting the time of their need. There is never a time in the life of a human being when his teeth, and all of them, are not needed. In childhood their need is paramount.

Among the first voluntary muscular actions of the child after birth is that of the muscles of mastication. Long before the baby can hold up its head, or has gained control of its hands, the chewing muscles are well developed and vigorously used. In the act of nursing the work of these muscles is vigorous enough to call upon the heart for increased action to provide needful blood supply. Later, with the advent of the teeth, the muscles of mastication are given greater leverage, and their action becomes correspondingly more powerful. The force exerted by them on the skull, and the increased flow of blood to the head, with their added muscular activity, are influencing factors in the development of the bones and the shape of the face and head. The fulcrum of this group of muscles is the teeth. Only when the teeth are brought forcibly together, or come in contact with food in chewing, is the powerful strength of the chewing muscles brought out. The generous blood supply which these muscles demand flows freely not only to the muscles, but the brain, too, receives its share. Experimental research with animals has demonstrated that, by interfering with the functions of the teeth, the shape of the skull and face can be modified, and the strength of its sides made to vary. An added fact which shows the damage done by neglect to attend to the temporary teeth works harm at the highly important developmental period of childhood. Between the sixth and twelfth years the mouth needs particular attention. In these years tooth-decay proceeds rapidly if the mouth is neglected. Nutrition is interfered with; and tooth-rot from diseased teeth and foul discharges from inflamed gums and roots lower the child's vitality.

Thorough mastication prevents overeating; it assists in regulating the quantity of food needed to maintain normal metabolism. The stomach is not overtaxed; and no part of the nutritive value of food is lost. Nor are the physiological processes of digestion and assimilation hindered by the formation of undesirable chemical products. The soft and delicate lining of the stomach is not suited to do the work of the mouth; nor is it intended that it should. The effect of chewing upon the teeth themselves is that decay is retarded in the mouths of those who chew food with proper deliberation; and strong teeth are developed by the exercise of chewing. The teeth and the jaws need to be used; and they need good blood to feed them, for their perfect development, just as much as the arms and legs need exercise. Mastication restrains the craving for unsuitable food; and it divides food into small particles so that it can be swallowed easily, and handled promptly by the digestive juices. Chewing of food sets into activity the flow of saliva, and, in turn, the action of the saliva establishes an agreeable taste. An agreeable taste of food in the

mouth starts the secretion by the stomach of its digestive juices, and the stomach is made ready to begin and carry through its part of the process of digestion. If well chewed, starchy food continues to be digested in the stomach. If not thoroughly mixed with the saliva, only partially chewed, these foods undergo fermentation, and disorder begins at the very beginning of the sustaining process of digestion. Children must be taught the habit to eat slowly, and to chew food until it is soft and moist and can be swallowed easily. Once thoroughly taught it becomes a life habit.

Hunger and appetite are intimately interrelated. Hunger is a dull ache or gnawing sensation referred to the region of the stomach. The body's first strong demand for nutriment, if unsatisfied, is likely to grow into a highly uncomfortable pang, less definitely localized as it becomes more intense. Besides the dull ache, lassitude and drowsiness may develop, or faintness, headache, irritability and restlessness, and to such extent that continued effort in ordinary pursuits becomes increasingly difficult. Appetite is related to previous sensation of taste and smell of food. Taste is made unreliable by a diseased mouth and decaying teeth. Appetite may exist separate from hunger, when delectable dainties are eaten merely to tickle the palate. Sensory associations, delightful or painful, determine the appetite for any food, and memory can arouse desire or dislike for certain foods. Underlying the idea that hunger arises from a general condition of the body is the fact that, as time passes, nourishment disappears from the blood, and, consequently, the nerve cells demanding food give rise to the hunger sensation.

Hunger is not always referred to the stomach. It is not due to emptiness of the stomach; it is not due to the digestive juices secreted by the empty stomach; it is not due to swelling of the glands of the stomach which make these juices. Hunger is the result of contractions of the stomach and other parts of the digestive canal. Contractions of the stomach precede sensations of hunger—they are the real source of the hunger pang. When the empty, healthy stomach is manifesting periodic contractions the intestines, too, are active. All parts of the digestive canal composed of smooth muscle share in these movements. The lower esophagus is provided with smooth muscle, and the periodic activity of these two regions—stomach and esophagus—is simultaneous. Otherwise the stomach would force its gaseous contents up into the mouth. What causes the stomach to contract is not definitely known, but though the contractions do not seem to be directly related to bodily needs, habit, no doubt, is an important factor. This might explain the presence of hunger at meal times, which is natural. The regularity of normal defecation indicates that the alimentary canal has habits. In dogs that were fatigued the rhythmic contractions of the nutritive canal failed to appear. Which gives a rational explanation of being "too tired to eat." Recent significant observations have shown that the stomach discharges its contents more rapidly if food is eaten in hunger than if not so eaten. In other words, hunger is normally the signal that the stomach is contracted for action; the unpleasantness of hunger leads to eating. Eating starts the

secretion of the stomach juices, distends the contracted organ, initiates the movement of digestion in the stomach and abolishes the sensation of hunger. Meanwhile, the digestive juices in the intestines are preparing to receive the oncoming nourishment. The periodic activity of the digestive canal in fasting is, therefore, not solely the source of hunger pang, but at the same time it is a signal in the digestive organs of readiness for prompt attack on the food swallowed by the hungry person.

The intestines—the third factor in nutrition—bring one more illustration of the paradox that the world knows little of the greatest contributor to health. The regularity of defecation is natural; the lower part of the digestive canal—the bowel—has its habits. Constipation is a bad habit—a habit which, too often, the child is permitted to acquire. Constipation is not inherited. The first and best aid to health is a regular daily movement of the bowels. They should be moved, and properly relieved and emptied at a stated time. In the morning, immediately before or after breakfast, is the time to relieve them. Health is defined as a harmonious adjustment of all the organs. When the bowels are neglected there cannot be harmonious adjustment. Too great emphasis cannot be given to the importance of forming and maintaining the bowel habit; nor can it be emphasized too often. Without it no child can be well.

An illustration will point this fact, and it will show the courage it sometimes demands to carry home this truth. Seldom can be found a more striking instance in which a situation has to be handled with more strength and decisiveness to overcome traditional indifference:

A little girl five years old—an only child—for a year or more had convulsions frequently. Naturally her mother was most anxious, and she had sought advice from doctors as to what could be done to relieve the distress of both the child and the parents. Aside from an assurance that her child would outgrow the attacks, the mother could find no help. The child was irritable, peevish, and nervous to the extremest limits; it was impossible to manage her. She had never attended school; she was not thought well enough to go to school. So quarrelsome and disagreeable was she that her playmates and the neighbors were unable to tolerate her, even with all the patience and pity granted to a sick child. She was well developed, and looked to be fairly well nourished. Physically the child was sound and normal; she had no physical defects. Closer investigation revealed that physiologically the child was not normal. Obstinate constipation was present; she had always been constipated—so much so that the fullest adult doses of the most active laxatives were required to effect a movement of the bowels. Naturally, these heroic drugs were not resorted to until utmost necessity demanded. The child refused to take any medicine that did not "taste good."

Her sleep was uneasy, restless, and broken by night terrors; and at frequent and uncertain intervals violent convulsive seizures came. These seizures alarmed the mother. The child had a dry mouth. Chewing paraffin (an inert gum without chemical action) produced no secretion of saliva, not even enough to be obtained by a dropper inserted in the mouth after vigorous and continued chewing. Her mother stated that the child always had difficulty in swallowing. Consequently this small girl had acquired the habit of washing her food down with milk and later with weak tea. She had a brave appetite, and ate greedily all kinds of food and all the sweets and candy she could get. At night, when her father came home to his hearty dinner of rich food, the child took her place at the table and ate her fullest share of the meal.

So completely had the mother failed to teach the child

the bowel habit that heroic measures had to be taken. The mother's protest against a bowel medicine which had an undeniably bad taste was answered by telling her that it was to be taken because it did taste badly; and by that very token her child would begin to make more of an effort to try to help her bowels move naturally. A nurse, who was tactful, patiently forceful, and ingenious in resources, was installed in the home for the definite period of two weeks. She was to initiate a new habit with the child—to establish the bowel habit; and to organize the undertaking for the mother to adopt and maintain. In ten days my plan had succeeded. Definite, practical instructions were given the mother as to the right food, in kind and quantity, for her child, and stated times at which it should be taken. The child's mouth needed attention; the toothache of which she complained not infrequently was eliminated by prompt attention to the decaying teeth.

Within the following month the report was that the child's bowels were continuing to act naturally—without a laxative; that there had been no convulsions; that she slept soundly, naturally, and completely relaxed—as every normal child sleeps; that she was less peevish and irritable; and she was unbelievably more easy to manage. To the mother's immense wonder, the child was really "drooling"; all difficulty in swallowing dry food had disappeared. A chemical examination of the saliva revealed a normal salivary secretion in constituents and quantity. Another examination of the urine showed greatly improved metabolism. The child's disposition had undergone an unbelievable change for the better; her behavior was greatly improved. She grew to a normal weight which was maintained steadily. Immediately the child was sent to school, and double promotion came at the end of the first year. Again, two years later, came double promotion without any particular effort to secure it. Six years have passed and during that time only five convulsive seizures have come, each seizure following immediately upon a debauch of sweets (intestinal auto-intoxication) and excessive excitement. The last attack was in June, 1915, and was only a light one.

It is a difficult undertaking to hold a pampered child always to no candy, no pie, no tea, and not too much excitement, and particularly when the undertaking is started against a five years' handicap. This child has a sheet-anchor out in a good bowel-habit securely fixed.

The three factors in nutrition, the condition and work of the buccal-gastrointestinal tract, must be investigated searchingly if the source of disease is to be discovered—if the fundamental cause or causes are to be sought out and dealt with, and if metabolic disorder is to be completely, or, more or less permanently, corrected. A failure of the mouth or stomach to do its full mechanical and physiological part in the process of digestion puts a burden on the intestines which does not belong to them, and which they cannot carry. Harmonious physiologic adjustment in the nutritive process fails, and auto-intoxication is the result. Auto-intoxication from long-continued digestive disturbances does not loose its grip unless team-work of the entire alimentary tract is reestablished. Particularly is this true with the neuroses. Using the broadest possible working knowledge of general medicine, and with patient and painstaking search to discover all the facts, the neurologist studies the child and its habits and environments. He seeks to know the whole story. Each child is an individual problem, to be studied and treated as such.

Neuroses of children fall under three types: The Nervous Child; Chorea; and Epilepsy. Not infrequently nerve disorders begin early in the child's life. Over 40 per cent. of more than 7,000 pupils referred to the Department of Child Study in Chi-

cago were found to be nervously depleted, malnourished, uneducated in the fundamental bodily activities, lacking in bodily control, dull at voluntary initiative, and with a weakened power of resistance. Even among school children who are mentally normal there is much nervous instability. Fully 50 per cent. of the medical problems in child life exist when the child is first registered for school.

The nervous child is not physically fit. Nervousness is a condition which can be taken too lightly; if it is not checked in season more or less serious consequences may follow. It is so common a condition that it seems needless to have the doctor see the child—all he will say is, "the child will outgrow it." Instead of being an unalloyed joy to the home the nervous small boy or girl becomes more and more a tax upon the patience of every member of the household, and an anxiety and much more of a burden upon the mother than a child need be. When such a child is sent to school a generous part of the increasing burden is shifted to the teacher, a young woman with small first-hand knowledge of children, and without the authority, time or experience to correct the physical shortcomings of even one of the two or three or more score of children whom she is employed to teach. The school is expected to do what the home has failed in doing.

The conservation of the nervous system cannot be begun too early in the child's life. To make certain a sound nutrition is the first duty to the child. Once established, the boy or girl begins life right. This demands a constructive program that involves work, the expenditure of effort, if anything of value is to be accomplished. Without intelligent and persistent effort the obstacles which are obstructing the pathway of the child are not cleared away; the child cannot go forward as it should. Just as close attention needs to be given to the nutrition of the growing child after infancy—between the second and eighteenth years—as during babyhood. Yes, closer attention, because from two years on the nervous system is developing; its functions are establishing themselves and the emotions are coming forth and being shaped for use and control. Any neglect of nutrition makes poor bodies. Poor bodies make slow minds.

Children with chorea or St. Vitus' dance put upon the doctor a problem which is difficult to work out. The difficulties are increased because, generally, malnutrition has a long lead. Bad habits, faulty and damaging feeding, and mismanagement and a more or less complete failure of discipline have obtained over a considerable length of time. These conditions, all of which must be corrected, too often have become so well established, they sit so tight that to unseat them demands a severe tax upon the patience, time, resources, tact, and courage of the doctor and the impatient mother and child. The mother unconsciously grows impatient because the girl or boy has drifted beyond her control. Not infrequently St. Vitus' dance develops at or near the adolescent period of childhood. Puberty is a turning point in the child's development—a vital, crucial period of life. Any disturbance of the nervous balance at this particular time augments the difficulty in correcting it. Harder is it to escape a permanent damage which must needs be carried throughout life. Records of 65 children

with St. Vitus' dance show that 45 of them were girls, and 20 of them boys; and of the girls 37 were between 6 and 14 years of age. Of the boys 19 were between the same ages.

With St. Vitus' dance one of the difficulties is to reveal each to the other—the mother and the child—as they really are; to clear away misunderstandings. These misunderstandings sensibly affect progress in curing this disease; they work for retarding it. When a mother brings her child for treatment for this nervous disturbance she is quite sure to say to her unruly child, "Now *you* listen to what the doctor says." Children do not listen to what the doctor says when they are taken to see him. Either they are too much afraid of him to listen, or they are quite as busy in measuring up him as he is in studying them. They must learn to like him and trust him before they begin to listen to what he says. It is the mother who must be talked to. She must be told clearly and definitely what she is to do toward getting the child well. Even though she protests, she is the one person who is really to do the hard work; and she must do it. She must be the responsible agent whose duty it is to carry out definite instructions, simply and clearly stated, as to the child's food and living habits. A survey of 90,000 pupils in the Boston Public Schools discovered that 5.5 per cent. had St. Vitus' dance, and 90 per cent. of these children came from "good" homes.

The conditions which make for St. Vitus' dance have not been discovered. The causes have not been determined. There are those who prefer to accept the theory that this nervous disturbance is due to infection; but as yet no specific infective agent has been found and isolated to strengthen that theory. In intensive study of certain facts in chorea there appears to be a relation of cause and effect. Malnutrition is always present. A diseased mouth, a disordered stomach, or inactive bowels, and often all three of these central factors in malnutrition are present and active. Granting the theory of infection as the cause of St. Vitus' dance, a diseased mouth with actively discharging abscesses is, undeniably, a source of infection. And the ages at which children have this disease are when tooth-decay is most common, and the mouth very generally carries abscesses. Infection which poisons the entire body is accompanied by a total cessation of all movement of the digestive canal.

There is no need to sketch in even roughly the picture of epilepsy. Everybody knows the distressful features of the "falling sickness." Epileptics are shunned and avoided; they are outcasts. Only pity is given them, and that at long range. They are denied school opportunities; they are refused honest employment and work. To the seemingly hopeless task of helping them carry their burdensome infliction no one wants to set his hand. Which ever way they turn they find nothing to help them keep the faculty of effort alive; there is never any encouragement to make it live. Life is being continually whittled down into despair. An epileptic said recently: "The poor devil who has fits has no friends." There is no sickness the treatment of which is more widely known than that of epilepsy. It is the bromides, of course; tradition has established that. The doctor tries his hand, and gives

one form of the drug, or it may be another form; it is always the same drug. Finally the last hope is the three bromides; what one of them fails to do the three combined will certainly do—or fail. And they do fail. Nothing more can be done. The doctor gives it up. With a drug habit added this misfortune becomes a curse.

This academic attack upon epilepsy is from the wrong quarter. It deals only with the end results; it stupefies. It does not strike at the cause or causes. In epilepsy, as in all nerve diseases, the three central factors of nutrition must be considered—the mouth, the stomach, the bowels. Not a single one of them should be overlooked. Malnutrition with its certain damages is the responsible causative factor in this disease. Call it autointoxication or infection, as you will, malnutrition is the cause to deal with. Immediate attention given to secure physiological intestinal activity, establishing regularly-timed, normal, daily emptying from the intestines of the products which cause autointoxication is the first step in the treatment of epilepsy. Persistent and patient effort, along with the right kinds of food and exercise, achieves and maintains a natural bowel-habit—one which is released from dependence upon drugs. If the mouth and stomach need attention, they should be put into good condition straightway. Every physiological and physical defect should be searched out, and so far as possible they are to be corrected. Careful laboratory analyses (quantitative, qualitative, and microscopic) of the twenty-four hour amount of urine and saliva, made from time to time, determine the metabolic activity of the alimentary tract. Analyses of the secretions aid substantially in determining and directing progress. An equally important factor, and one which cannot be omitted, is an intimate study of the individual, his living habits and environment.

The responsible cause or causes of this disease are dealt with. In the disheartened victim faculty of effort begins to stir; it is alive. It has not been drugged. He is being helped to help himself. Pressing the attack upon the disease, on the basis of nutrition, and against the end at which stands the cause, the seizures come less often, and with diminished severity and less exhaustion. Which would seem to point to a way leading to more or less permanent relief from a burdensome malady. One fact is determined—a possible means of prevention and protection.

Now and then a tragedy falls heavily upon a community—a tragedy which shocks us. Recently a young man, who to every appearance was physically sound, took his own life under hard stress of new and exacting work and discipline. Three times in the week preceding he reported at the hospital and declared he could not stand the work. A thorough medical examination showed nothing the matter except that he was "highly nervous." Thus he was pronounced, and the incident was disposed of as closed. The personal equation was ignored. Such tragedies are preventable. Nervousness is a term which is used loosely, and which is freely spoken. There is a vagueness concerning it, partly because we have not learned fully what the normal expression of the nervous system in our bodies is. In further search and progress our

attention needs to be turned to the prevention of nervousness and the neuroses. The surest way, certainly the shortest way to meet these problems, is to help the child in every way to begin life with a nervous balance and control which cannot be unseated—to help the child escape nervous disaster; to attack the problem in the very beginning. Comfortable, controllable nerves can be enjoyed at any age, and in any state of health. They have medicating virtues of their own; they provide a vigor of body and mind which give the strength and endurance demanded to put us equal to our tasks.

The old family physician knew human nature; he knew *his* people. He had the time to talk with and instruct the young, inexperienced mother about *her* baby and the children. He has passed on. But his work, his peculiar office, remains; and his work has grown. It has been amplified until now, in these days of specialized service, his work falls to the prenatal nurse, the school doctor, the school dentist, the school nurse, and the specialist. To medical school inspection—the school doctor, the school nurse—is given the responsibility of being the binding links which make the closer bond between the home and the school, the parents and the teacher. Through closer sympathies and understandings, and human cooperation, a large field in preventive medicine stands forth. In this field belongs, along with the other health conservation activities, in its place, the work for the prevention of nerve disease.

32 NORTH GOODMAN STREET.

THE SANITARY CONDITION OF MIKVEHS AND TURKISH BATHS.*

BY WALLACE A. MANHEIMER, PH.D.

NEW YORK.

SECRETARY, AMERICAN ASSOCIATION FOR PROMOTING HYGIENE AND PUBLIC BATHS.

(From the Research Laboratory, Department of Health, New York City.)

MIKVEHS, strictly defined, are Jewish ritual baths. The term "mikveh," however, as commonly used by the Jewish people includes baths of similar type, though not always of a purely ritual nature. Accordingly, mikvehs can best be classified as (1) sanctioned mikvehs (true mikvehs, sanctioned by the Rabbis) or Jewish ritual baths for women and (2) unsanctioned mikvehs divisible into (a) common mikvehs or plunge baths operated at elevated temperatures and used as cleansing baths and (b) cold plunges operated in conjunction with Turkish sweat rooms.

The first study of the sanitary conditions of mikvehs was that of Mr. H. F. J. Porter,† who reported, in 1912, on their polluted condition. Mr. Porter urged the writer to investigate these baths more thoroughly and as a result, preliminary studies were published‡ in 1914 and 1915. In 1914 the New York City Department of Health invited the Jewish Community (Kehillah) to cooperate in the formulation of plans to effect the sanitation of the mikvehs,

*The details of the inspections were carried out by Mr. David Lehman and Mrs. Theresa Ybanez, both of the Research Laboratory.

†*The Survey*, July 27, 1912.

‡*The Survey*, April 18, 1914, and Aug. 28, 1915; *Journ. Inf. Dis.*, Vol. 15, No. 1, p. 159.

the writer being asked to act as consultant. Plans were drawn up which met with the approval of both the Department of Health and the Board of Authoritative Rabbis of the Jewish Community. In order to carry out the details of the plans, the Jewish Community formed an organization of the mikveh owners, and the dues from the members of this association were used to pay an inspector whose duty it was to enforce the sanitary and religious regulations.

The members of the "Mikveh Owners' Association," as it was called, were put to considerable expense and trouble in carrying out the sanitary regulations, but it was felt that the publicity which would be forthcoming through the auspices of the Jewish Community would so arouse public sentiment in favor of the clean mikvehs, that both the expense and trouble would be justified. Furthermore, the Department of Health contemplated a thorough inspection of mikvehs, from which inspections immunity would be enjoyed by the members of the Mikveh Owners' Association. The publicity, however, was of a meager nature and the inspections of the Department of Health were interrupted through unavoidable causes. The mikveh owners who were members of the Association obtained scant, if any benefits from their membership and accordingly ceased to pay the quarterly dues. The inspector had to be discharged and in due course the society disbanded.

I. *The Sanctioned Mikveh.*—The Sanctioned Mikveh, as already stated, is the only true mikveh, its use being a necessary part of the Jewish ritual. Stringent Talmudic laws govern the use of the ritual plunge, which if carried out in letter and spirit would make sanitary inspection and control of these baths entirely unnecessary. The ritual dip is required of women at all periods within seven days after menstruation, prior to certain holidays, before marriage, etc. Men are not required by religious law to take the ritual dip, although certain sects of Jewish people have acquired the custom of using the mikveh as a semi-religious practice.

Inspections and Bacteriological Analyses.—There is in each establishment usually one plunge of about 200 cubic feet capacity, containing water maintained at somewhat higher than body temperature. The daily attendance is small, rarely exceeding 30 and usually about 15. The cost of baths in these mikvehs varies between fifteen and fifty cents, the majority being low priced. While the baths are usually reserved for the exclusive use of women, some permit the use of them by men at certain times in the day. The women following, therefore, bathe in the same water previously used by the men.

A mikveh to be sanctioned must be under the supervision of a Rabbi, and the bath taken in it must be taken with due regard to the numerous religious tenets governing the ritual dip. Most important among the religious requirements are those which demand scrupulous cleanliness of the body before ablution in the mikveh is permitted.

On the whole the premises of this type of bath are in fairly good sanitary condition. The bacterial data collected from analyses of the water, however, indicate quite clearly that more frequent renewal and periodical disinfection are necessary.

BACTERIAL DATA FROM MIKVEH CLASS I.
BACTERIA IN 1 C.C.

	Agar 37° C.	Gelatin 20° C.	Coli in Bile	Temp of Water ° C.	Approximate attendance
1	79000	190000	100	36	10
2	1900	8500	1	35	5

8	320	650	1	35	1
9	2700	1400	100	32	..
10	30240	16000	10	35	25
11	945	21200	10	34	5
12	260	300	0	34	5
13	1400	4700	1	35	8
14	158	1800	10	38	8

Accordingly all the baths were treated with various concentrations of calcium hypochlorite for the purpose of ascertaining the most efficient quantity of chemical to use. One ounce per 900 gallons proved to be satisfactory under the conditions of application which obtained. As a routine the sanctioned baths (those that were members of the "Mikveh Owners Association") were periodically disinfected and daily renewed with clean water.

Conclusion.—Concerning the sanitation of the sanctioned mikveh, a careful regard for the management of the water, including its daily renewal (or more frequent renewal if used by more than 20 persons daily) and its periodical disinfection,* together with the providing of clean towels, liquid soap, individual drinking cups, sanitary control of premises, etc., should prove adequate to effect suitable sanitary conditions.

II. *Common Mikvehs.*—The common mikveh consists of a plunge bath, the water of which is maintained at an elevated temperature. This type of bath is frequented for the same reasons as Turkish baths, the mikveh plunge being used as a common cleansing bath by a large number of people.

Inspections and Bacteriological Data.—These mikvehs are located, usually, in tenement houses, where they occupy the ground floors and cellars. Some, however, are located in loft buildings, in yards of tenement buildings, and a few in stables. A separate coal furnace for hot water is invariably on the premises to supply hot water for the mikvehs, tub baths, and shower baths, if present. Coal, wood, straw, litter, and debris of all kinds have been observed about the furnaces, which constitute a grave fire hazard, especially when it is recalled that most of these mikvehs are in tenement houses, accommodating, at times, as many as twenty large families. Concerning the fire hazard for those using the mikveh, conditions are very bad. The approach to the mikveh is frequently by means of a narrow wooden staircase leading down to the cellar, where the bath is located. Destruction of the stairs would cut off the only means of egress for the bathers. Occasionally the public press has reported fires in these establishments which have fortunately terminated, up to now, without fatality. Nevertheless, the fire hazard in these baths, as well as in those described in Section III, is of grave character and worthy of drastic control.

*The disinfection of the water of these baths by the use of an ozone-generating machine is contemplated and the details of the experiment will soon be arranged.

Reliable data on the number of individuals who use the baths cannot readily be obtained; observation, however, showed that large numbers frequent them. Indeed, as many as 300 people have been observed to bathe in a plunge containing a like number of cubic feet of water! The presence in the immediate vicinity of free municipal baths has operated, through salutary competition, to reduce the profits derived from mikvehs, and some of the mikvehs have suspended operation entirely. Since the majority of these baths are not of a purely ritual nature, such competition should be encouraged and the free bathing facilities for the people in those communities greatly expanded.

44	320	250	50	28	5

In most instances the pools consist of tile-lined tanks sunk in the ground and are about 5 feet deep by 6 feet square. Few mikvehs contain over 300 cubic feet of water, the majority containing approximately 175 cubic feet. Most of the establishments have more than one of these plunges, which they operate at different temperatures, the bathers first immersing themselves in the water of that containing the lowest temperature and finally going to the one having the highest. The temperature of the water varies considerably. The highest temperature observed was 55° C.* Most, however, are operated at between 40° C. and 45° C., although numerous instances of water at 50° C. were observed. The water is changed at the end of a day's use, if its appearance absolutely demands it, but is never changed during the day in spite of its being

*The hot water for these baths is frequently added by a pipe emptying onto the surface of the water. This accounts for the high temperatures obtained. A few temperatures at the bottom were taken and they registered from 5° to 10° C. less.

used for common bathing by a large number of people. It was not possible to collect samples of water always at the time of maximum pollution, but the table indicates sufficiently polluted water.

Common combs and hair brushes, cake soap, and common bathtub brushes are usually supplied. Dressing room compartments are of wood and not vermin-proof. In some of the establishments rows of couches are supplied, as in the mikvehs of Class III (see Section III). In most of these places only bathtubs are supplied for those who desire to take a preliminary cleansing bath, but these tubs are not much used because of an extra charge of 5 cents. Showers are rare and when present have been observed in several instances to empty into the plunges. Bathtubs when used are not carefully cleaned for the next patron and are frequently left to stand for considerable lengths of time full of filthy water, until the attendant has time to empty them. The chains on the stoppers are frequently broken and for this reason the attendant must thrust his arm into the filthy water and remove the stopper. A superficial cleaning of the tub ensues to put it in readiness for the next patron. Poorly laundered towels are frequently supplied, and at times roller-towels for common use provided.

From the hygienic standpoint these very hot baths are just as devitalizing as the Turkish baths (see Section IV) and are not recommended by leading hydrotherapists. Taking into consideration the filthy condition of the water, the insanitary conditions of the premises, the fire hazard, and the devitalizing influences of the baths, I feel justified in concluding:

1. That the shower baths, as far as possible, replace the common bathtub, which, if continued to be used, however, must be cleaned adequately after each bath.

2. That increased bathing facilities be provided in the vicinities where these mikvehs exist. That shower bath facilities be provided in the basements of settlement houses, public schools, and other public buildings.

3. That these mikvehs, if allowed to continue business, be carefully supervised as to their sanitary condition.

4. That this type of plunge bath be abolished through the passing of a law preventing the taking of a cleansing bath in a plunge used by more than one person.

III. *Mikvehs with Turkish Sweat Rooms.*—These are border-line mikvehs, partaking of the character of both mikvehs and Turkish baths. They are primarily poor grade Turkish baths provided with a cold mikveh plunge, and without the services of masseurs. In the common mikveh (Class II) sweating results from immersion in the hot water of the plunge, whereas in these establishments "sweat-rooms" are provided, which are heated with steam and hot air.

Inspections and Bacteriological Data.—The individuals who use these baths disrobe in a large room and place their clothing either on benches or in small wooden lockers. These lockers are not ventilated and are not vermin-proof. The bathers then proceed to the sweat-room, where they remain, seated on long wooden benches until they have sweated to their satisfaction, after which they take

a brief dip in the cold water of the plunges. Some elect to omit the dip in the mikveh, taking a cleansing bath instead.

The plunges in these establishments are not used extensively and do not represent so grave a sanitary menace as those described in Class II. In regard to the sanitary condition of the premises, however, these baths present an even poorer picture than those already described.

In particular the sleeping accommodations supplied to patrons deserve mention. The couches are placed close together, usually in poorly ventilated rooms* and in large numbers. Sheets, pillowcases, blankets, and quilts are laundered infrequently and provided for common use. Bed linen in positively filthy condition was observed on the couches.

The bacterial data (see table) from the water of these baths show no striking contrast with those obtained from the previous group of mikvehs. The length of time the water is permitted to remain in the pool probably explains the rather high counts. The water, however, from general appearance seems to be in much better condition, especially since it does not contain the detritus from the body which literally covers the surface of the water in the common mikveh (Class II).

61	240	340	30	30	2
62	88000	11000	1	30	12

*The women attending the baths, always use the pool.

In one particular only, namely, the appearance of the water of the plunges, do these baths surpass those of Class II; in all other details of sanitary condition they are on a par with them.

Conclusions.—1. The plunges in mikvehs with Turkish sweat-rooms should be operated in pre-

*As instances of poor ventilation we cite two clippings from a New York newspaper.

"Six men were overcome by coal gas in a Turkish bath establishment. The coal gas was generated by a furnace used for supplying steam for the sweat room."—*The Sun*, Jan. 2, 1917.

"One young man was killed and five overcome by coal gas from the furnace in a Turkish bath."—*The Sun*, Jan. 3, 1917.

cisely the same way as swimming pools. The water in them should conform with the bacterial standard for swimming pool water and should receive periodical disinfection in a manner similar to that recommended for sanctioned mikvehs (Section I). Preliminary inspection of bathers and a preliminary cleansing bath should be required.

2. Adequate supervision of the premises should be maintained. Proper ventilation should be secured. Individual bed linen, towels, brushes, combs, etc., should be provided.

3. Elimination of fire hazard for both the bathers and the dwellers in the tenement should be secured.

Turkish Baths.—Turkish bath establishments present a far better appearance than do the mikvehs with Turkish baths, although the ones inspected ranged from rather poor class places to those having the finest appurtenances and up-to-date conveniences. Concerning their hygienic features leading balneologists condemn them.

From the sanitary standpoint, fortunately, their condition is fairly good, only certain elements of their procedure requiring correction.

Inspections and Bacteriological Data.—The swimming pools operated in conjunction with the Turkish baths were examined in the winter and were at that time in fairly good condition (see table). In the summer, however, they are used more extensively, and the conditions would probably not be so good.

SWIMMING POOLS IN TURKISH BATHS.

No.	37° C.	20° C.	Coli. in Bile.	Temp. of water.	Approximate attendance.*

72	5	18	0	cold	50
73	104	750	0	cold	35

*Attendance here refers to the number of people using the Turkish Bath. There was no way of telling how many used the plunge.

Concerning the sanitary condition of the premises and bathrooms, our reports were generally favorable, clean bedding, bed linen, and properly laundered towels were supplied. Only in a few particulars could objections be raised, as, for example, use of common drinking cups for supplying ice water to the patrons in the sweat-rooms, the use by the masseurs of common brushes for washing the patrons, the ungloved and possibly contaminated hand of the masseurs, and the poorly cleaned marble slabs upon which the patron lies while being washed. In addition to these details it should be pointed out that the baths are used during the day by women and during the night by men, and the sleeping quarters get such continuous use as to preclude proper airing of the bedding.

Conclusions.—1. The common drinking cup provided in the sweat-rooms should be abolished and replaced by sanitary drinking cups.

2. The common scrub brushes used by the masseurs should be replaced by individual brushes or hempen wads that can be sterilized after each separate use.

3. Marble slabs should be thoroughly cleaned and hosed off before use by a second patron.

4. The masseur should be required to wear gloves for his own as well as the patron's protection and these gloves should be sterilized after individual use.

5. Turkish baths are harmful from the hygienic standpoint, and their use should be discouraged.

2350 DAVIDSON AVENUE.

OBSERVATIONS ON COMPLEMENT FIXATION IN TUBERCULOSIS.

BY WILLIAM MEYER, M.D.,

WEST HOBOKEN, N. J.

CHIEF OF CLINIC, DEPARTMENT TUBERCULIN THERAPY, WEST SIDE GERMAN DISPENSARY, NEW YORK.

THE diagnosis of incipient tuberculosis is a difficult problem. The problem is still harder when it comes to the diagnosis of active incipient tuberculosis, *i.e.*, to tuberculosis that requires treatment, eliminating quiescent or healed lesions. This difficulty has, in conjunction with the x-ray and other means, been almost overcome by the complement fixation. The multiform clinical manifestations of tuberculosis and the extreme variations in its course in different individuals affected, are the obstacles in the way of an early diagnosis. The variability of the disease may be sought for in the susceptibility or individual resistance, showing numberless temporary fluctuations. Wherever a definite diagnosis cannot be made, it is a good axiom, at least to suspect tuberculosis. Tuberculin does not tell us whether a given case may or may not require special attention; it only tells us: Here is tuberculosis—whether quiescent, healed, or active.

The complement fixation has this, however, in common with the tuberculin test: The majority of lethal and late third-stage cases give negative results, probably due to the same underlying principle of which we shall speak later. There was, on the other hand, one great difficulty to overcome in the successful employment of the complement fixation test, namely the lack of proper antigens.

Besredka and Manouhling finally succeeded in cultivating tubercle bacilli on a different medium than that used formerly. On this nutrient the organisms manifested properties hitherto not observed. This fact led Besredka to try the antigenic properties of these cultures for the deviation test. He then found that in from 90 to 95 per cent. of clinical cases of tuberculosis the result was positive.

Besredka's medium, used for this purpose, is prepared in the following manner: Dilute the white and the yolk of an egg, each separately, with 10 volumes of water, then filter. The yolk solution must be clarified by slowly adding sodium hydroxide. Autoclave both solutions and keep them separate. Before using them, mix 10 volumes of sterile alkaline veal in fusion (prepared without peptone, salt, or glycerin) with 2 volumes of the sterile white of egg solution and one volume of the sterile, clarified yolk solution. Put this mixture into sterile test-tubes ready for use. Most strains grow with ease in the course of a few days on this medium, but it is essential, although requiring some labor, to make it fresh shortly before inoculation.

Certain fluctuations, for instance in the chemical composition of the egg, may alter in consequence thereof the chemical composition of the antigen. Hence it becomes necessary to increase or decrease the amount of alkali or the amount of tuberculin used for the test in each batch of antigen. It is well to keep in mind the strain specificity in tuberculosis, when making these tests.

Dr. Miller suggested and worked out an easier method which has the advantage over the other antigens that it saves labor and keeps better.

Dr. J. Bronfenbrenner and others found the test position in 84 per cent. in first-stage cases of tuberculosis, in 94 per cent. in second stage, and in only 15.3 per cent in third-stage cases. This low percentage in third-stage cases is probably due to the fact that there is no new antibody formation, due to the exhaustion of resistance in the patient, and that the circulating antibody is taken up as formed by the combination which may and does greatly increase during the last stage of the disease.

To make the test it is necessary to have fresh serum, which is titrated for the amount of complement present. This titration is performed with erythrocytes washed and previously sensitized with one unit of amboceptor. To overcome the presence of antish sheep amboceptor, naturally present, the antihuman hemolytic system must be used.

Now titrate guinea-pig serum for its complement content, using human red cells sensitized as before. Add enough guinea-pig serum to bring up the amount of complement already present in the human serum to 2 units. Now add the antigen and incubate. After the incubation is terminated, red cells sensitized with one unit of amboceptor are added and again incubated, when the hemolysis becomes evident.

The proper amount of amboceptor for this test is determined as follows: Take 6 to 8 graduated test tubes, pour into them amboceptor solutions up to 0.1 for No. I test tube; 0.15 for No. II, etc., then add physiological salt solution to each test tube up to 0.8 c.c., now add 0.2 c.c. of the 50 per cent. suspension of washed human erythrocytes. Incubate for 30 minutes on a water bath at 37° C., shaking the tubes at short intervals. This will result in 1.0 c.c. of a 10 per cent. suspension of red cells sensitized with varying amounts of amboceptor. After $\frac{1}{2}$ hour distribute 0.025 c.c. of fresh human serum (human complement) into as many test tubes as there are dilutions of amboceptor and bring up the volume in each of these tubes to 0.9 c.c. Each of these tubes should now receive red cells sensitized with gradually increasing amounts of amboceptor, *i.e.*, transfer to each of them 0.1 c.c. from the various tubes above given. Now we have a number of tubes, each holding 1 c.c. of 1 per cent. suspension of blood cells, sensitized in the presence of varying amounts of amboceptor, and 0.025 c.c. of human serum. Incubate $\frac{1}{2}$ hour at 37° C. and read the amount of hemolysis in the different tubes.

The smallest amount of amboceptor which has sensitized 0.1 c.c. of 10 per cent. red cells so that they are completely hemolyzed by 0.025 c.c. of fresh human serum, constitutes one unit of amboceptor.

This test, as stated above, indicates active tuberculosis and more so when repeated at intervals of one month for 2 or 3 times. There are cases that are

negative now and positive one month hence and again negative the third month. These are borderline cases and need close watching. Arrested and cured cases show a negative reaction, so do most late third-stage cases.

TABLE I.
220 tests, showing the following results:

	Human.	Bovine.	Wassermann.
Class I. 56 cases	4 +	(18) 2 + (9) + (7) ±	(2) ±
Class II. 42 cases	3 +	(5) + (2) ±	(3) ++
Class III. 28 cases	2 +	(1) ±	0
Class IV. 40 cases	+	(9) 2 + (2) + (3) ±	(4) ±
Class V. 11 cases	±	0	(1) + (5) +++
Class VI. 53 cases	0	0	(2) ++ (2) ±

Note: Numbers in brackets indicate number of cases; sign ± means doubtful.

I formed a table reviewing the blood tests of 220 cases, some repeated 2 or 3 times, covering a period of 7 months or more. A large number of these tests were made by the New York Board of Health, Division of Diagnosis. This table also shows the Wassermann reaction wherever present, also the stage of pulmonary cases and cases under suspicion.

TABLE II.
Showing parts affected and stage:

	Glands.	Lungs.	Bones.	Skin.	Eyes.
Class I. 56 cases	27	15 1st stage, 13 2d stage, 2	9	3	2
Class II. 42 cases	11	23 1st stage, 15 2d stage, 4 3d stage, 4	5	2	1
Class III. 28 cases	3	25 1st stage	0	0	0
Class IV. 40 cases	2	38 1st stage, 22 2d stage, 14 3d stage, 2	0	0	0
Class V. 11 cases	5	5 1st stage	1	0	0
Class VI. 53 cases	0	18 late 3d stage, 15 early 3d stage, 3			

8 first stage gave —.
5 second stage gave —.
9 showed Wassermann —.
26 showed no disease whatever.

Conclusions.—Cases with tuberculous glands or bones showed a higher percentage in 4+ human type than pulmonary cases; this holds good also in bovine type, namely 2+ or simply 1+.

The third-stage cases (pulmonary type) that showed + were all early third-stage cases, all late third-stage cases were negative.

Some cases were + one month and negative the next month or vice versa, these cases were all anæmic, had lost weight and complained of fatigue, but showed no signs of disease by x-ray or other diagnostic methods.

The luetic condition nowhere interfered with the tuberculosis deviation test, since those that reacted

to both tests showed unmistakable signs of active tuberculosis.

The biologically treated cases became negative in 82 per cent., a case showing 4+ human and 2+ bovine having been treated with a mixture of human and bovine tuberculin for 3 or 4 months, for instance, would under a new test show human + and bovine ± and be negative a few months later.

Out of 89 pulmonary cases, 5 increased the + by 1 or 2 and the bovine, originally —, became + in one case after 3 months' treatment, but became — again under continued treatment, all other cases showed a continuous decrease in the + reaction.

436 CLINTON AVENUE.

Medicolegal Notes.

Mental Capacity of Epileptic Employee.—In an action for injuries sustained by a railway porter when he was seized with epileptic convulsions and fell from the train, the pleadings and the evidence raised questions as to his mentality; whether he had mental capacity to appreciate the dangers of the service; whether the defendant employed him with knowledge of his affliction, or should be charged with notice thereof; whether by reason of his affliction he was incapable of performing his duties; whether he was assigned to duties beyond his mental capacity and comprehension that were dangerous to him by reason of his want of mental capacity and his affliction of progressive epilepsy; and whether he had knowledge that he was incapable of performing his duties when he applied for employment. It was held that the trial court properly refused to direct a verdict and submitted the case to the jury.—*Young v. Southern R. Co.*, South Carolina Supreme Court, 94 S. E. 302.

Supervening Negligence of Patient.—In an action for malpractice the Wisconsin Supreme Court holds that where the defendants were negligent in the treatment of the plaintiff before she left the hospital in which she had been treated, and damages resulted therefrom, the fact that the plaintiff aggravated the result by conduct after leaving the hospital prematurely would not bar recovery, but would go in mitigation of damages. The plaintiff's negligence was rather subsequent or supervening negligence than contributory negligence.—*Schultz v. Tasche* (Wis.) 165 N. W. 292.

Homicide Provoked by Assault.—Under a policy insuring against death sustained through external, violent, and accidental means, without any specific or definite exception covering the matter, the intentional killing of the assured by a third person does not of itself withdraw the claim from the protection of the policy. The test of liability is whether the assured, being in the wrong, was the aggressor under circumstances rendering a homicide likely as the result of his own misconduct. An assured wrongfully assaulted another person with a pole three or four feet long, and pursued the fight with a pistol, which he first fired, and was then himself shot and killed. It was held that the homicide was not accidental within a policy insuring against death by external, violent or accidental means.—*Clay v. State Ins. Co.* (N. Car.) 94 S. E. 289.

Public Health Regulations—Infantile Paralysis.—The federal district court for Vermont holds that a regulation promulgated by a state board of health prohibiting fairs, Chautauquas, street carnivals or circuses until further notice, when based upon the professional opinion of the members of the board, physicians from different parts of the State, that such gatherings are likely to cause the spread of infantile paralysis, is a reasonable regulation within the police powers of the State, and not invalid as in violation of the constitutional provision against impairment of the obligation of contracts, although its effect may be to prevent the performance of contracts.—*Community Chautauquas v. Caverly*, 244 Fed. 893.

License to Practice Osteopathy—Scope.—That a license to practice osteopathy does not confer the right to remove tonsils and give medicine in connection with the operation is held in *State v. Bonham*, L. R. A. 1917D, 996.

Military Medicine.

ASTHENIC STATES AT THE FRONT.

CHEYRON states that the scientific curiosity of the medical man at the extreme front cannot well be satisfied. Not only are the actual demands upon his time extremely insistent, but the observation material is eminently fugacious. The men in the trenches have their especial maladies for which they may have to be evacuated. With epidemic maladies stamped out by hygiene, the troubles encountered are chiefly respiratory or gastroenteric, and in a lesser degree comprise skin diseases, nephritis, trench diseases proper, and pathological fatigue.

The last-named condition is made the subject of the author's study. Among its manifestations, lumbago is the most frequent, and this incidence bears some relation to the use of excavating implements. In addition to mere pain, the subject is unable to flex his trunk, and a rest, recumbent, for at least 24 hours is necessary for his recuperation. A higher degree of backache follows either a prolonged or strenuous sojourn in the trenches. Fever up to 104° is present, and characteristic, in that it fluctuates irregularly without any typical curve. The general stiffness and soreness of the muscles and the extreme weariness, form, with this fever, a triad of symptoms. The term "fatigue fever" is a useful one, the play of temperature between 101.5° and 104° being due essentially to fatigue. Naturally, the tongue is foul, and anorexia and constipation coexist with occasional nausea and vomiting. The pulse is accelerated, and there are headache and severe pain referred to the rear of the eyeballs. Herpes febrilis and nosebleed are encountered at times. The syndrome is decidedly professional in type, and while it may usher in infectious diseases is none the less a separate entity. As a result of this deep fatigue the digestive apparatus may become disorganized, with a local reaction or autointoxication. The initial constipation is succeeded by violent diarrhea or attacks of colic. In addition to poison from this source the blood must be loaded with fatigue toxins. As a result, the action of the kidneys is compromised, albuminuria appears, and the severe pains in the back may be in part due, in a given case, to actual nephritis. There are marked hypotension and much irregular functional behavior of the heart, to which is sometimes added actual heart failure (syncope, cyanosis) as a result of total exhaustion. The patient, after syncopal sensations, falls flat and has to be revived with analeptic drugs and procedures.

Fatigue is doubtless due in part to adrenal exhaustion, and in a certain percentage of cases definite evidences of the latter are present. However, the cerebrum seems to be the essential seat of the fatigue, and while the entire body is involved the author appears to believe that the fibers in the white matter suffer most, comparing them to battery wires which become unequal to the transmission of potential beyond a certain degree. The psyche may react with states of fear and psychasthenia in general, neurasthenia, extreme depression, hypochondria, hallucinatory states of peculiar type (seen especially in sentinels), sleep disorders, etc. In battle, men often think themselves badly wounded while still intact. Convulsions are sometimes seen.

Commotional and confusional symptoms occur, and it is essential to discriminate between psychasthenia and psychoses. The former term must refer to an acquired state which occurs on a normal substratum, but which presents phobias, obsessions, impulsive acts, aboulia, etc., similar to those seen in psychopathic individuals. As results of war fatigue these manifestations are new, at least to the modern generation, and due, in all likelihood, to the peculiar character of the present mode of warfare with drum fire, gas attacks, etc. It will be no easy matter to decide between the psychasthenic and psychotic manifestations which occur side by side in the greatest profusion.

War Malaria.—There appears in *Le Progrès Médical* for December 8 a sort of impromptu symposium on this subject with five leading articles. Bernard regards malaria as second in importance to none of the war plagues. Not only was it of the highest significance in the warfare at the Dardanelles, Salonica, and Macedonia, but from these foci it has been transplanted throughout the whole of France. This author gives a complete general review of the subject which does not lend itself to a brief epitomization. An extensive bibliography is appended. Certain paragraphs are of special interest. Quinine has been used heroically and cinchonism has occurred in an unprecedented degree, but the general symptoms pale into insignificance in comparison with the local accidents which follow intramuscular injections of the drug into the buttocks. Large and deep abscesses and extensive sloughing are accidents often recorded and illustrated. The distinction between primary and secondary malaria is carefully maintained throughout. Owing to the fact that quinine tends in time to lose its efficacy we are confronted by a special type of quinine-fosi or quinine-resistant paludics to whom large doses and intensive treatment may be necessary when relapses occur; for in these subjects the drug will no longer prevent relapses.

Leenhardt and Tixier write on the treatment of malaria in a special center. They make use of the intramuscular treatment with which one of the authors has become thoroughly familiar in Morocco. The results are remarkable, for not only is an access at once arrested but old cachectic subjects show a remarkable general change for the better in a few days. Moreover, these injections cause a quinine retention and those physicians who have tried the oral exhibition with its manifold prejudices to the gastroenteric tract of the anemic subject—who needs the full use of his digestive apparatus—must prefer the newer method even although this too has its drawback. Most striking is the fact that patients as a rule choose the intramuscular route. The authors in over 5,000 injections did not see a single abscess. There was one case only of hematoma with secondary sloughing. Of immediate, as distinguished from remote, accidents syncope is occasionally seen, but has no specific character, since it may follow any puncture. Blood examinations may furnish indications. Thus in a severe infection with the blood swarming with hematozoon 0.80 gm. of quinine hydrochloride is thrown into the buttock

daily for eight days. Although a systematic plan of treatment will cleanse a patient thoroughly he is not necessarily sterilized and prognosis is the worst part of the management—one is never certain that the disease will not reappear after a severe infection.

Leger and Mouriquand write briefly on the hibernation of the anopheles in the Dauphiné as studied during the past winter, which was very rigorous. The larvæ of the anopheles were seen at intervals throughout the entire cold season. In the hibernating state they resisted with ease water temperatures of 13° C. and underwent the usual change to nymphæ. Nymphæ taken from the water developed in the laboratory into active adult individuals in two days. This was in April.

Garin and Pasquier conclude from a study of hospitalization that hospitals for malarial subjects should have an altitude of 1,000 meters in order to protect the civilian population. Bernard contributes a second paper on two cases of autochthonous malaria by which term he refers to cases in natives presumably infected from returning troops. The term has also been used to indicate a recrudescence of old native malaria in the war zone. With the idea that these subjects might be promptly sterilized he treated them with neosalvarsan injections in increasing doses. The immediate results were all that could be desired.

Women's Hospitals in France, Serbia, and Salonica.—Dr. A. Louise McIlroy writes in the *Glasgow Medical Journal* for November, 1917, concerning the work of a unit of the Scottish Women's Hospitals in France, Serbia, and Salonica. She says that various methods of treatment for dysentery were tried in Salonica. As it was of the bacillary form emetine was useless. Enemata of tannic acid, or Condy's fluid were given, also saline transfusions, but it was finally decided that the administration of drachm doses of sulphate of magnesia hourly until all trace of blood or mucus had left the stools was the most successful. Barley water was given by the mouth, with occasional administration of meat juice later. No milk in any form was given until convalescence was reached. If the stools were frequent and exhausting, the sulphate of magnesia was suspended for a few hours, and a small dose of morphine was given to insure sleep. This treatment was found to be the most efficacious of all employed. Cases of paratyphoid, typhoid, epidemic jaundice, and other diseases with gastrointestinal localization were also treated in the hospital. During the whole summer attacks of diarrhea were prevalent among the armies and also among the hospital staffs, and it was with great difficulty that the work of the various units could be maintained. No published conclusions have been arrived at as to the origin of this diarrhea. The water supply of the armies was boiled or chemically sterilized. That it was an air-borne disease may justify consideration, as new arrivals sometimes became infected when kept in the harbor in ships for several days before landing. The extreme heat and the prevalence of flies bore a considerable part in its maintenance as it disappeared with the onset of the colder weather.

During the late summer the climatic conditions

were more favorable and the health of the armies became excellent. Sand fly fever was almost the only disease experienced, but the attacks were of short duration. The symptoms resembled those of influenza, with headache, rise of temperature, aching joints, and a peculiar pain across the diaphragm. Treatment by sodium sulphate and aspirin was very successful in its cure.

In the autumn of 1916 an advance of troops took place in all the fighting front, and wounded began to pour into the hospital. During the whole winter and spring the hospital was full of surgical cases of very great interest. Much time was spent over accurate localization of projectiles in the tissues, and in this way much saving of tissue was obtained at operations, as division of muscles was rendered unnecessary when foreign bodies were accurately located. The cases were received from the firing line about twenty-four or forty-eight hours after injury. In some of these sepsis had already commenced, more especially those of the knee or elbow joints. The limb with its shattered tissue was cleaned up by immersion in saline baths before operation. Immediate operations on admission were not found advisable, unless in special urgent conditions. In this way the patient got over the shock and fatigue of the journey, and the after-results of the operation were more favorable. On arrival the bed-ridden cases were undressed and bathed in the wards on a bed protected with blankets and waterproof sheeting. Their clothes were immediately placed in a labeled sack and carried to the vestiaire to be disinfected, washed, and mended, and were only given back to the patient on his evacuation. Wounds were dressed immediately and the patient was permitted to sleep after being fed. Patients requiring urgent operations should be attended to in the clearing hospitals and should not be sent down to the base in a condition requiring immediate operation on arrival. The journey to Salonica through Macedonia from the front is difficult and arduous and the wounded arrive in a state of fatigue. After rest the patient is taken to the x-ray department, where the diagnosis and localization of projectiles and fractures are made. Operations are arranged for according to the urgencies and necessities of the condition.

Military Medical Research in France.—The American Red Cross has issued a statement concerning the appropriation of \$100,000 for medical research in France in which it quotes from the report of the commission in Europe and from a cablegram signed by forty-one army medical officers showing the propriety and need for the expenditure. The report of the commission states that "an extraordinary opportunity presents itself in France for medical research work. To carry on the work special laboratory equipment, suitable buildings, and animals for experimental purposes are needed, which at present cannot be obtained through ordinary Government sources without delay, which makes that source of supply quite impracticable. This recommendation, like all others, was submitted to an advisory medical board in France, composed of American doctors working with their own forces. They approved it.

The question has been raised as to whether the appropriation for medical research was not outside the scope of Red Cross activities." To this the Red Cross replies that the supreme aim of the Red Cross is to relieve human suffering growing out of war. There are many unsolved medical questions of great importance in this war. Numerous problems relating to the treatment of wounds, the eradication of lice, fleas, and scabies, the treatment of trench nephritis, trench heart, war neurasthenia, exhaustion, lethal gases, shell concussion, wound infection, compound fracture, and a great variety of other diseases and injuries are still to be worked out. The solution of such problems will contribute not only toward the relief of suffering, but toward more effective prosecution of the war. Scientific experience is conclusive that the most rapid possible approach to such solution is through medical research.

Antivivisectionists Oppose Inoculation of Soldiers.—The National Antivivisection Federation has sent a telegram to Representative Warren Gard, at Washington, protesting against the injection of typhoid, smallpox, and other serums, for the purpose of immunizing the men in the army camps. The telegram alleges that the inefficiency of the Army Medical Corps is the cause of the many deaths in the camps and charges Surgeon General Gorgas with "neglect in maintaining the practice of inoculation that is fraught with these grievous consequences."

Hospital Trains for American Soldiers in France and England.—Surgeon General Bradley announces the completion of plans for the care of American wounded in France. Fifteen complete hospital trains have been ordered in England and two in France, and more will be ordered later. The plans provide ample hospital service for every wounded American soldier.

Health in Training Camps.—For the week ended January 18, the sick rate in the National Army and the National Guard camps shows a slight increase. Deaths in the National Army numbered 149 as against 147 for the preceding week, and in the National Guard 66 as against 88. Of the deaths, 100 in the National Army and 46 in the National Guard were due to pneumonia.

Maternity Hospital Supplies for France.—Dr. Eliza Taylor Ransom of Boston has completed plans and is about ready to sail for France with maternity hospital supplies sufficient to maintain a maternity hospital for one year. The outfit will include 5,000 layettes for poor French women, of which Dr. Ransom will take 1,000 with her. Dr. Ransom is going under the direction of representatives of the French Government.

Scope of Medical Training Extended.—Extensions are being made to the scope of medical training at Fort Oglethorpe, Ga., and Fort Riley, Kan. In addition to courses in general military surgery, genitourinary surgery, and surgery of the brain, head, and face ten courses either have been or are being established for the following: (1) x-ray specialists; (2) orthopedic surgeons; (3) psychologists; (4) special examining surgeons; (5) sanitary engineers; (6) veterinarians; (7) sanitarians; (8) hospital administration; (9) laboratory specialists; (10) dental surgeons. There

are at present 5,400 officers and men at Fort Oglethorpe and 3,800 at Fort Riley. The ultimate needs of the Medical Department of the Army look to training camps with a capacity of 35,000 to 40,000 officers and men. There have been graduated from the training camps since June 1, or are now under instruction, 9,000 officers and about 20,000 enlisted men.

Cape May Hotel for War Hospital.—The Cape May Hotel, which cost its builders \$1,350,000 in 1909, has been leased by the War Department for hospital purposes at an annual rental of \$99,000. The hotel has 600 rooms.

Mental Tests for All Soldiers.—Surgeon General Gorgas has announced the decision of the War Department to extend the psychological examinations to all the enlisted men and to all newly appointed officers of the army. Special buildings and equipment will be established in each army cantonment, and a school of military psychology will be established at the medical officers' training camp at Fort Oglethorpe, Georgia, where fifty military psychologists will be entered monthly for a course of training. The purpose of the tests is to aid in segregating and eliminating the mentally incompetent, to classifying men according to their mental capacity, and to assist in selecting competent men for responsible positions. The work will require four commissioned officers and twenty enlisted men per division in order to examine four hundred men a day. The total estimated personnel required for conducting the examination in thirty-one divisional camps and for a special staff in the Surgeon General's Office is 27 majors, 51 captains, and 54 first lieutenants of the sanitary corps of the national army and 62 sergeants, 62 corporals, and 620 enlisted men.

War Ration in Capsule Form.—Food experts have worked out a war ration containing 2,400 calories, which is compressed to about the size of a dog biscuit, sealed and waterproofed, so that it can be carried in the soldier's pocket ready for emergency. This ration contains wheat flour, meat, and dried milk. With the ration goes a paraffined package of peanut butter. The weight of the ration is four ounces. It will be made a part of each man's equipment.

Medical Units Ready to Serve.—The statement said to have come from the Surgeon General's office that there is a shortage of at least 20,000 men in the enlisted personnel of the Medical Corps has caused some expression of astonishment on the part of members of medical units that are prepared and anxiously awaiting the opportunity to serve. Attention is called to the fact that fully equipped units are ready for service at Rochester, Syracuse, Albany, and elsewhere in New York and also in other States. There are a number of units splendidly equipped in New York; in Brooklyn, for example, there is a unit that it is said has for many months been anxiously awaiting a call. Not very long ago it was announced that no more commissions would be given in the Medical Reserve Corps until further notice, and subsequently it was stated that a number of medical officers had been discharged. This is puzzling.

MEDICAL RECORD.

New York, February 2, 1918.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE annual report of Surgeon-General Gorgas for the fiscal year 1917 has just been issued. Attention is drawn to the fact that the geographical range and the variety of the activities of the medical officers of the army have increased greatly during the past ten years, and especially since the entrance of this country into the World War. As evidence of the unprecedented expansion of the activities of the medical department of the army it may be stated that at the time the report was presented there were more than 13,900 officers engaged in the work of the department, including officers of the regular Medical Corps and the four officers' reserve corps—Medical, Dental, Veterinary, and Sanitary—under the direction of the Surgeon-General.

The general health conditions of the army for the calendar year 1916 were satisfactory. The mean strength of the entire army, American and native troops, including the National Guard, was 176,803 for the year 1916. Its non-effective rate from all causes in the year was 24.26 per 1,000, and for disease alone 20.55, both of which ratios were slightly lower than for the previous year. The admission rate was 858.87, as compared with 726.22 for the previous year; the discharge rate was 15.22, as compared with 14.06 for the previous year; and the death rate was 4.39, as against 4.45.

With regard to typhoid fever in the army, it may be stated that the efficacy of antityphoid inoculation has been conclusively demonstrated. Since vaccination has been in vogue typhoid fever has appeared only sporadically in the army, usually less than a dozen or so cases a year. Antityphoid inoculation and properly enforced sanitary and hygienic measures have controlled effectually the spread of the disease. Vaccination has been as effective also against paratyphoid as against typhoid fever.

Malarial fevers show a non-effective rate of 0.62 for 1916, as compared with 0.54 for 1915, the lowest non-effective rate in the history of the army. The result proves the efficacy of the antimalarial measures instituted by the sanitary officers of the army some ten years ago. In 1906 the non-effective rate for malarial fever alone was 2.55 per 1,000.

Measles occurred among the troops in 1916 with considerable frequency, and in the report an earnest warning is uttered against the overcrowding of troops, particularly of recruits and fresh levies in their tents, camps, barracks, and cantonments. A warning, we may remark, which was not heeded, with the results which are now well known to the country. Some one is responsible for these needless deaths, and whoever he is he should be exposed, and not allowed to "pass the buck."

Tuberculosis still holds a foremost position among the causes for disability discharge from the army, and stress is laid in the report upon the desirability of early recognition of the disease, especially at recruit stations and depots for applicants for enlistment.

Venereal diseases continue to cause a great deal of disability. However, particular emphasis is laid on the falsity of the assumption that illicit intercourse and venereal diseases are more common in the military forces of the United States than in civil life. The admission rate for alcoholism in the army stationed in the United States for the year 1916 was 12.33 per 1,000, which is lower than for the preceding year, when it was 13.07.

It is believed that at least 24,000 medical men will be included in the personnel of the medical department of the army when full strength is attained. The work thrown on the department will be immense, but judging from the manner in which matters have proceeded up to the present time there is reason to hope that our fighting men will be cared for as probably no army has ever before been cared for, provided always that authority be given to the medical officers to enforce their regulations. In this respect a very bad beginning has been made. We may be 3,000 miles away from the war, as has been said, but the cantonments and camps are here, and the death rate among the troops crowded in them is already disgracefully high, for the sole reason that the recommendations of General Gorgas have been ignored.

THE PROBABLE CAUSE OF FATALITIES IN TONSIL-ADENOID OPERATIONS.

DEATHS during or immediately following operations for the removal of tonsils and adenoids are fortunately rare; but an occasional case is reported and there are doubtless far more that are never reported than that are. In an article in the *Practitioner* for November, 1917, Mortimer takes up this subject and considers that the immediate fatalities are due mainly to: (1) faulty administration of the anesthetic; (2) respiratory obstruction; (3) shock, and (4) hemorrhage.

Before discussing these various factors Mortimer calls attention to one error whose magnitude is sometimes realized only when it is too late, namely, lack of proper preparation. In this connection he feels that while the operation is generally undertaken to remedy conditions of ill health which will cease only after the operation in ques-

tion has been done, there are many cases in which the patient should be put in better condition before operation. As he says, "Anemia, rickets, and, in adults, excessive smoking, alcoholism, and so forth, can at least be amended to some extent, not to mention other innumerable disorders." Fright, exposure to cold, fatigue, and injudicious feeding are other unfavorable and easily remediable factors.

In discussing faulty administration of the anesthetic, Mortimer considers the chief errors to be: (1) Failure to select the appropriate anesthetic; (2) want of knowledge, so that a deep anesthesia is taken for a light one; (3) failure to maintain a free airway and attend to the respiration and the circulation; (4) failure to regulate or change the anesthetic when circumstances alter, and (5) overdosing, absolutely or relatively. He says that shortcomings on the part of the anesthetist are more likely to have serious results when this operation is being done than during many others of greater surgical importance because the breathing is often impeded and irregular, anesthesia must be arranged to allow the surgeon access, sometimes a deep degree is required, and the anesthetist must act to some extent as the surgeon's assistant by steadying the head and the gag and must know his methods. The anesthetist's attention is therefore somewhat distracted, and yet he should watch narrowly the respiration, color, pulse, and pupils, especially since the anesthesia sometimes deepens after the operation has been started because of interference with elimination on account of respiratory obstruction.

Under the heading "Respiratory Obstruction," he calls attention to the fact that the patient starts with a handicap, since the tonsils and adenoids encroach upon the breathing space; hence care must be taken to keep the throat clear of blood, clots, and fragments of tissue, otherwise a heart already fatigued may be overstrained or blood may be sucked into the air passages. Shock, by which he means "a condition clinically serious, brought about by abnormal peripheral stimulations," is uncommon when the tonsils are enucleated quickly, but when they are dissected out shock "is more likely to come on gradually and to be combined with the effects of previous hemorrhage and of respiratory obstruction and perhaps of overdose of the anesthetic." Hemorrhage receives but brief mention, the reader being referred to an article by McKenzie (*Practitioner*, August, 1917) for a full discussion of this phase. However, he calls attention to the fact that fatality from concealed hemorrhage may take place through faulty position of the patient after operation. This, which may easily be avoided by keeping the patient in the prone or semiprone position until he recovers from the effects of the anesthetic, is a particularly lamentable cause of fatalities. Regarding status lymphaticus as a cause of death, Mortimer says that he

regards it with the same suspicion as "idiosyncrasy," for he has observed that in many reported cases the disasters might have been otherwise explained. Late fatalities, such as those due to the pneumonias, are not discussed.

In most of the cases of immediate fatalities from tonsil-adenoid operations, Mortimer believes that one has to deal with a combination of causes and conditions; but, as he says, "at the same time it is of first importance, with a view to resuscitation, to estimate the proportions of the various factors and to distinguish, for example, a case of pure shock from one of blood in the larynx—in short, to make a diagnosis—and to do this when possible as soon as danger threatens, not to wait until it arrives."

As we said in the beginning, deaths during or immediately after these operations are rare, but they are far from being so rare as the comparatively small number of reported cases would seem to indicate. "For this very reason," Mortimer says, "and because an unexpected death in the young is so distressing, public attention and alarm are aroused to an exaggerated extent when one does occur." We also agree with Mortimer in the statement that the operation and the giving of the anesthetic are too often undertaken by those who have no special skill or experience to justify them; and though death may not ensue, the operation is bungled and life unnecessarily risked.

THE USES AND CAUSES OF PIGMENTATION.

THE function of cutaneous pigment is to protect the skin from chemical and photochemical noxæ. The greater the amount of pigment in the skin the less the power of the actinic rays to injure it. But it also appears to have a certain protective action against mechanical insults, for we find that the repeated application of flaxseed poultices brings about a defensive pigmentation and the pad of a truss causes the same reaction. Melanine, the pigment of the skin, is found in the nucleated cells of the rete in a varying degree. In the negro individual granules of melanine cannot be made out, the entire cell being uniformly tinged as if the melanine had gone into solution. When melanine is isolated it is found to be of various hues—reddish brown, black, deep purple; nevertheless, it always has the same chemical composition and is one and the same substance in all races. The granules of melanine are formed within the nuclei of the cells, from which they migrate.

It is universally admitted that in the fair races pigmentation depends on several factors—the general state and resistance, nutritive and functional activity. One whose skin pigments quickly is in good state, reacts quickly in defense of the organism. Jeanneret and Messerli (*Revue médicale de la Suisse romande*, November, 1917) in an elaborate study of the relations between heliotherapy and pigmentation are not in agreement with the physiologists as to the active function of pigment. The saturation with pigment of the skin of the African

at most protects him, they hold, from overheating, from insolation. He derives no benefit from heliotherapy in any diseased state. We know that light is absorbed by the lipochromes and red blood cells and that this mechanism is involved in heliotherapy. The authors have treated deeply pigmented Brazilian aborigines without benefit. They do not refer to the theory which has been advanced that not the presence of pigment, but the superior activity of the negro skin protects the subject from overheating.

On the subject of the lessened resistance of blond races to certain diseases, especially tuberculosis, the authors add that heliotherapy by reason of their feeble pigment reserves is less efficacious in blonds than in those of medium and dark complexions. They can predict by the color of the hair the probable pigment reserve and response to treatment. But this is not the sole factor. The red blood corpuscles or, in other words, the hemoglobin index, play a rôle in resistance to disease and response to solar therapy. With hemoglobin normal the outlook is much more favorable for resisting disease, and light treatment should also bring up the hemoglobin index. Heliotherapy increases the pigment in the skin and while rapid response shows good resistance, the converse is not true, for some who pigment very slowly secure ultimately the desired results. In such cases the hemoglobin index is high and there is absence of any factor which tends to produce anemia. Despite the apparent independence of hemoglobin and melanine in the body the authors feel certain that the latter is derived ultimately from the former.

RETENTION OF URINE FROM A BULLET IN THE URETHRA.

MANY bullet and shell wounds of important structures, in which the foreign body has been accorded an astonishing degree of tolerance by the tissues, have been reported during the present war. For example, in approximately a score of reported cases the heart itself has tolerated for weeks or months shell fragments or bullets in its walls or, rarely, even in its cavities. But one of the most remarkable cases, reported by A. Robin (*The Practitioner*, September, 1917), is one in which a bullet became lodged in the urethra without either the patient or the surgeons being aware of its presence in that situation until it caused retention of urine.

Robin saw this patient about the middle of March, 1917, after he had been transferred to the Sidmouth V. A. Hospital under the diagnosis of "nephritis." There was a small amount of albumin in the urine and he came with a number of other men in the same convoy who had well marked symptoms of nephritis, the urine containing blood and numerous casts. On the night of his arrival his temperature rose to 104° and he had retention of urine. When preparing to pass the catheter the surgeon found a metallic substance presenting at the orifice of the urethra, acting as a ball valve. The follow-

ing day the man was anesthetized and the foreign body was removed with a bullet forceps, no incision of the meatus being necessary. The foreign body was found to be a complete German bullet with the point presenting.

A short summary of the previous history makes the case seem all the more remarkable. Upon his arrival at the Sidmouth Hospital neither the patient nor his papers had given any indication of his having been wounded; but upon questioning him later it was found that he had been wounded in the left hip about six months previously. He had been taken to the hospital at Etaples, where he had remained three weeks. There was but one wound, but the patient stated that no x-ray plates had been taken. Six or seven weeks after he left the hospital he began to have abdominal pain, which later extended to the genitalia. There was at that time no difficulty with the bowels or bladder. Later, he reported sick several times and received treatment. About January 1, 1917, he began to have frequency and difficulty in micturition; yet there was apparently but little pain and instruments passed on two occasions met no obstruction. He was suspected of malingering and a court martial was mentioned. About the middle of February, when reporting sick again, he was labeled "nephritis" and sent to the base hospital at Sidmouth, where he was seen by Robin. After learning this history, a further examination was made and a small, circular scar was found in the region of the left anterior superior spine of the ilium, evidently the point of entrance of the bullet.

EVOLUTION OF THE ANTIMONY TREATMENT OF INTERNAL LEISHMANIASIS.

THE first use of antimony for parasitic infections goes back to 1906-7, when its resemblance to arsenic led to its try out in trypanosomiasis. Soon brilliant cures of human trypanosome disease by intravenous injection of solution of tartar emetic began to be reported, and now a considerable literature of the subject has accumulated. The use of the remedy in espundia and Oriental boil goes back only to 1913, when it was at once extended to granuloma venereum. In 1915 the injections were first given in infantile leishmaniasis interna and kala-azar, and over a score of papers have been written on this subject alone. Claims of priority having arisen, Jemima shows in *Il Policlinico* for December 9 that Caronia and Di Cristina are entitled to full credit over Castellani and others for the demonstration of specificity of antimony in kala-azar and internal leishmaniasis in general.

THE PROBLEM OF BILHARZIOSIS IN VENEZUELA.

BILHARZIOSIS is a serious menace in Venezuela, and it is important to obtain a survey of the incidence before any concerted attempts can be made to minimize it. Dr. Rísquez of Caracas, in an article abstracted in the *Revista de Medicina y Cirugía de la Habana* for November 25, gives an account of his efforts in this direction. He has collected a small bibliography, which comprises published articles and official documents. The literature does not go back

of 1906, in which year Soto reported 3 cases. Apparently, 173 cases have been recorded during the entire period, not a large number, at first sight, but nearly all of the material has seen the light in 1915-16 (1917 is not included). The author, as pathologist in the Medical School of Caracas, recorded 44 autopsy cases during 1915-16 which should represent a large number of infections. The material in the capital city comprised native citizens and not immigrants from the rural districts, while certain parishes showed much more infection than others. A comparison between Venezuela and neighboring countries plainly shows that the former is the only one in which the disease seems endemic. In the Ancon Hospital, Panama, only 38 cases were treated during 1905-1913 inclusive. There are but few cases in the whole of Colombia, and none in Cuba. No explanation is hazarded of the prevalence of bilharziosis in Venezuela.

News of the Week.

Physicians Requested to Report Occupational Diseases.—A recent *Bulletin* of the New York City Department of Health states that in its work for the reduction and control of so-called occupational diseases it makes extensive use of the information gathered as a result of medical and sanitary surveys in particular industries and of the medical examination of the workers at the occupational clinics. While this has produced excellent results, it would be of much greater service if physicians would report, as they are required to do, instances of occupational diseases coming under their observation. This information is desired not only for the correction of unhygienic and unsanitary conditions in some particular shop or factory, but to gain a complete knowledge of the hazards to which industrial workers are exposed in this city. All information thus obtained is strictly conditional. During the past year a total of only 130 cases of occupational disease have been reported to the Department of Health by hospitals and private physicians. It seems improbable that this represents all the instances of occupational disease in a population of 5,000,000. It is requested that not only such diseases as anthrax, caisson disease, lead poisoning, etc., be reported, but that other conditions, such as tuberculosis, pneumonia, asthma, bronchitis, circulatory diseases, nephritis, diseases of the skin, nervous diseases, and orthopedic defects, be reported when occupations seem to be a factor in causing them. It is especially important to report all cases of poisoning by lead, arsenic, mercury, phosphorus, bronze, wood alcohol, aniline, brass, acids, gases, bisulphide of carbon, and wood naphtha.

Lay Clerks for Clinics.—At the annual meeting of the Association of the Out-Patient Clinics of New York, held on January 25, Dr. Charles Hendee Smith read a paper recommending the employment of volunteer clerks in the clinics in order to save the time of the doctors and offset the loss of doctors who have left for war service. The Bellevue Hospital Out-Patient Department now employs about twenty volunteer clerks. It was

pointed out that the public is more than ready to respond to an appeal to help institutions that promote public health and welfare.

Child Welfare Associations Meet.—Representatives of the American and British Associations for the Study and Prevention of Infant Mortality met at the Ritz Carleton Hotel, in New York City, on January 25, under the presidency of Mrs. William Lowell Putnam, president of the American Association. Among the speakers were Miss Julia Lathrop of the Children's Bureau at Washington, Dr. Edward Clark, and Dr. S. Josephine Baker of the Bureau of Child Hygiene of the New York Department of Health, Dr. Morris Slemmons of Yale, and the Countess of Aberdeen, who outlined the child welfare work being done in the British Isles.

Appropriations from Rockefeller Fund.—The first budget of the \$10,000,000 fund to be spent by the Rockefeller Foundation has been announced. The largest appropriation is \$150,000 to be used in welfare work in the military camps under the supervision of the Commission on Training Camp Activities. The National Committee for Mental Hygiene receives an appropriation of \$37,000 for "surveys of public care of mental diseases and studies in the psychopathology of crime." The State Charities' Aid Association of New York receives \$6,500 for public clinics in New York State for the after-care of infantile paralysis. The China Medical Board receives \$11,430 to be used within five years for the maintenance of the two hospitals on the Island of Kulangsu. Provision is also made for bringing additional Chinese students to the United States for medical instruction. Provision has been made for the perfection of the program of the commission cooperating with the Red Cross and the French Government for the prevention of tuberculosis in France, the establishment of an additional unit for the relief and control of hookworm disease in Rio Janeiro, and the continuance of the investigation of malaria control in Mississippi.

Poison in Cosmetics.—The Bureau of Standards at Washington has issued a warning to the public to be careful in the use of hair dyes, rouges, hair removers, and similar cosmetics, because many of them contain poisonous ingredients. Hair removers are in general quite corrosive in character, and sometimes poisonous. Dyes used in blackening gray hair generally contain one or more of the salts of silver, lead, copper, iron, or bismuth and can cause serious poisoning when taken internally.

Milk for Babies and Invalids First.—The Ministry of Food of Great Britain has directed the local food committees to adopt a scheme for giving priority to the needs of infants and invalids and others for whom an adequate supply of milk is a necessity. The scheme went into force on January 21, and provides that milk shall be supplied only in priority to holders of priority tickets. Such tickets are issued only to the following classes of consumers: (a) Children up to 5 years of age. (b) Any person holding a qualified medical practitioner's certificate to the effect that such person is entitled for reasons of health to a certain specified quantity of milk per diem. (c) Any class of person medically recommended. The

quantities to be supplied for children are 1½ pints daily, if under 18 months of age, and one pint if between 18 months and 5 years. For other persons according to the medical certificate.

Pneumonia Deaths Decrease.—According to the records of the New York Department of Health there were for the week ended at noon on January 26, 342 deaths from pneumonia in a total of 1,732 deaths, as against 365 in a total of 1,812 for the previous week.

Veterinary Surgeons Recommend Horse Meat.—The veterinary surgeons of New York, Connecticut, New Jersey, and Massachusetts, at a conference in the New York Veterinary College, on January 26, adopted a resolution calling upon Congress to appropriate immediately \$100,000 to establish the inspection of horse meat. They point out that if this is done great numbers of horses and ponies on the Western ranges will be made available for food.

Doctors Raise Fees.—It is reported that the physicians of Elmhurst, in the Borough of Queens, have banded together and beginning February 1 will raise their fees. The schedule adopted makes day visits from two to three dollars and night visits from three to four dollars.

Boys on Extra Lunches Gain Weight.—The twenty-five boys from Public School No. 40, New York City, who are the subject of the experiment being conducted at the Post-Graduate Hospital to determine the value of school lunches, at the end of nine lunches have been weighed and 21 show gains. The greatest gain was two pounds and the smallest one ounce. The average gain was three-quarters of a pound each.

Dr. Edward L. Kellogg of Gouverneur Hospital, New York City, who was sued for \$50,000 damages, in 1910, by William Perlman, who claimed that he lost two toes because of the way in which an operation was conducted, has been acquitted and vindicated by the Supreme Court.

Charitable Bequests.—Under the will of Emil Wolff of New York about one-half a million dollars was left to charity in the form of shares in the Einstein-Wolff Company, each share being valued at \$100. The following institutions are participants in the bequest: Mount Sinai Hospital, 1000 shares; Montefiore Home and the Hebrew Charities, each 250; the Polyclinic, German, Lebanon, Beth Israel, Sydenham, National Jewish, Denver, Skin and Cancer, and St. Luke's hospitals, each 100 shares; the Hebrew Infant Asylum and Home for Aged and Infirm Hebrews, each 100 shares; the New York Eye and Ear Infirmary, 100; the New York Hospital for Bone and Joint Diseases, 50 shares.

Under the will of the late Charles Huber, the Twin City Hospital of Asbury Park and Dr. W. W. Beveridge each receive bequests of \$10,000.

Among the beneficiaries of the will of the late Joseph H. Choate are the State Charities' Aid Association, the New York Association for the Blind, and the Women's Prison Association, each of which receives \$10,000.

The Burlington County Hospital, New Jersey, is the recipient of a bequest of \$5,000, in trust, by the will of the late Richard L. Ashurst.

The first panel of the Sheriff's Jury of New York

City at its recent dinner at Delmonico's gave \$5,000 to the various hospitals of the city, instead of spending the money on souvenirs as has been its custom.

The Hahnemann Hospital, Philadelphia, has received a bequest of \$5,000 for the endowment of a free bed in memory of the testator's parents, under the will of the late Isabella Semple of Philadelphia.

The Hospital of the University of Pennsylvania has received a bequest of \$10,000 for the endowment of a perpetual free bed, under the will of J. Austin MacDowell of Philadelphia.

Prevention of Venereal Diseases in New York State.—A plan for the control of venereal diseases is being developed by the New York State Department of Health somewhat similar to that of the Social Hygiene Society of Oregon. A committee has been placed in charge of this work, composed of four members of the departmental staff and the secretaries of the American Social Hygiene Society and the New York Social Hygiene Society. The plans include an educational campaign directed to the lay public and also education of the practising physicians of the State and the medical staff of various institutions. If sufficient appropriations are available it is purposed to place treatment within the reach of all. An endeavor is being made to secure the cooperation of all private and semi-private institutions as well as that of public institutions. In the larger cities it is hoped that the local boards will establish venereal clinics; where this is not feasible the work will be done by health officers. The equipment for venereal clinics will be standardized and as far as possible all clinics will be brought up to these standards. At convenient points throughout the State means will be established for examination by dark field illumination and other laboratory facilities. It is hoped that means will be found of furnishing salvarsan substitutes to those who cannot pay for that drug.

Massage Operators Must Be Licensed.—The Health Department of New York City calls attention to the fact that few physicians know that there is a city ordinance which requires every person giving massage treatment, either manual or mechanical, with the exception of physicians, osteopaths, and registered nurses, to be licensed by the Department of Licenses. Applicants for a license have to prove certain qualifications and have a certificate from the Department of Health showing that the applicant is free from communicable disease. Both the license and the Health Department certificate must be shown to anyone on demand. This ordinance also requires that a massage operator, before giving treatment to a patient of the opposite sex in his or her office, must receive a written order from the physician, specifying the number of treatments to be given, not to exceed ten treatments to any one order. Physicians are requested to see that this ordinance is obeyed.

Advise Abandonment of Mohansic Site.—The joint legislative committee, which has been investigating sewerage conditions of the present site of the Mohansic State Hospital for the Insane and the New York State Training School for Boys at Yorktown suspected of being a menace to New York City's water supply, has decided to recommend the abandonment of the present site of the

Mohansic State Hospital and the retention of the Training School. The report to be presented will recommend that the erection of hospitals or institutions for the care of the insane on the watershed from which cities obtain their drinking water be forbidden. The opinion is expressed that there is no reason why certain other institutions should be forbidden the use of such sites.

Paris Notes Increase in Rabies.—The Health Board of Paris has notified the Prefect of Police that the frequent report of cases of rabies makes it desirable that measures be taken to check the spread of the disease. The Pasteur Institute reports that since the beginning of the war the number of persons bitten by dogs has increased, and that the institute is treating five or six times as many cases of rabies as before the war. The main cause for this increase is ascribed to the large number of vagrant dogs now in Paris as the result of the high cost of living, the raising of the dog tax, and the mobilization of many of the veterinary surgeons, which makes it impossible to inspect dogs as thoroughly as before the war.

Lawsuit against Vermont State Board.—Action has been brought against the Vermont State Board of Medical Registration by Dr. Anna G. Mack L'Homme of Boston to compel the board to accept her application to take the examination and to receive a license in case she passes the examination. Dr. L'Homme is already licensed to practise medicine in Maine. It is said that the suit is being brought to compel the State Board to recognize the College of Physicians and Surgeons of Boston, of which Dr. L'Homme is a graduate. The Board of Medical Registration is commanded to appear before the Supreme Court at the general term in Montpelier next May.

Dr. Charles Norris, chief of the laboratories at Bellevue Hospital, has been appointed medical examiner for New York City. Mayor Hylan was very persistent in his effort to perpetuate the old system by appointing temporarily one of the former coroners to the new position, despite the fact that the said coroner was unable to pass the civil service examination. In the meantime the Mayor tried through the municipal civil service commission to declare the three successful candidates at the examination ineligible to hold the office. But the civil service commission was too slow and before it had accomplished its object the period during which the office could be filled by the temporary appointment of an unqualified man had expired and the mayor was forced to obey the law. Dr. Norris was second on the list of successful candidates.

California's Medical Practice Act Upheld.—In a case appealed to the Supreme Court by two members of a religious sect claiming that the law was discriminatory against those who practised by prayer, the Court has handed down a decision that the State Medical Practice Act providing for licensing and regulating the practice of those engaged in healing the sick is constitutional.

Obituary Notes.—Dr. ALBERT KOHN died at his home in New York City on January 21, aged 48 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1891, a member of the New York Academy of Medicine, the Pathological Society, and many other medical organiza-

tions. He was attending physician to Mount Sinai Hospital, and formerly adjunct professor of internal medicine at the New York Polyclinic Hospital.

Dr. RICHARD GILES, a graduate of the College of Physicians and Surgeons, New York, 1882, died at his home at Cold-Spring-on-Hudson, on January 19, aged 57 years.

Dr. WILLIAM ELLERY JENNINGS, of Brooklyn, N. Y., died of pneumonia, on January 17, aged 43 years. He was a graduate of the New York College of Pharmacy and of Bellevue Hospital Medical College, in 1895. Dr. Jennings was for many years connected with the New York City Department of Health.

Dr. ABRAHAM STOUT died at his home in Bethlehem, Pa., on January 9, at the age of 87 years. He was a graduate of the Medical Department of the University of Pennsylvania, in 1855, and Surgeon to the 153rd Pennsylvania Regiment during the Civil War.

Dr. ARCHIBALD ALEXANDER HOWELL died at his home in Philadelphia, Pa., on January 11, aged 37 years. He was graduated from the Medical Department of the University of Pennsylvania, in 1908. He was instructor in medicine in the University of Pennsylvania and physician to the Presbyterian Hospital.

Dr. MORRIS HUGHES, of Kennett Square, Pa., a graduate of Hahnemann Medical College and Hospital of Pennsylvania, in 1884, and one of the organizers of the Homeopathic Hospital of Chester County, died on January 2, aged 64 years.

Dr. DANIEL P. MADOUX, of Chester, Pa., died of pneumonia, on January 3, aged 56 years. He was graduated from Hahnemann Medical College and Hospital of Pennsylvania, in 1883, and served as United States Pension Examiner.

Dr. ISRAEL H. BETTS, a graduate of Jefferson Medical College, in 1868, died of nephritis at his home in York, Pa., on January 6, at the age of 76 years.

Dr. JOHN S. PEARSON died at his home in Philadelphia, on January 5, aged 63 years. He was graduated from the Medical Department of the University of Pennsylvania, in 1876.

Dr. HENRY BIDLACK REED died at his home in Milford, Pa., on January 1, aged 67 years. He was a graduate of the Medical Department of the University of Pennsylvania and Assistant Surgeon of the 20th Regiment National Guard of Pennsylvania, during the riots of 1877, and of the Washington Grays Artillery Corps.

Dr. ROBERT LOVE MOORE, of Columbia, S. C., a well-known nose and throat specialist, died in the Columbia Hospital, on January 6, aged 46 years. He was a graduate of the University of Maryland, in 1896, and an ex-president of the Columbia Medical Society.

Dr. FLAVEL B. TIFFANY died in St. Luke's Hospital, Kansas City, on January 4, aged 72 years. He was a graduate of the University of Michigan, in 1874, and later studied in Europe. Dr. Tiffany was one of the founders of the University Medical College of Kansas City and occupied the chair of Ophthalmology and Otology in that institution for many years. He was also the author of several books, among them "Sojourn Among the Oculists of Europe," and affiliated with many medical societies.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

RED CROSS RELIEF WORK—DIFFERENCES BETWEEN FRENCH AND AMERICAN METHODS—CONSTRUCTION AND RECONSTRUCTION WORK.

PARIS, Dec. 24, 1917.

THE work of the Red Cross in France and Europe has greatly extended and expanded, and at the exposition being held at 136, Avenue des Champs Elysées there were daily addresses given by the heads of the departments, and special experts to acquaint the large audiences that gather with the scope and extent of the plans in view, which cannot but dissipate misunderstanding, and make for greater efficiency and success.

Mr. Homer Folks, director of the department of Civil Affairs, made an able exposition of the "Relief Work." As the basis of his speech, Mr. Folks made it clear that in trying to prevent the spread of tuberculosis and in the care for the children of France the chief aim of the American Red Cross was to save and strengthen the future of France instead of giving merely temporary relief to the sufferers, donations to the poor, or of preventing distress for the moment.

"Poverty, like tuberculosis, is preventable and curable," said Mr. Folks. "It can and must be prevented and cured. This is the spirit or the basis of the Red Cross work in America and we must bear in mind that our work is not so much for the individual as it is for the various groups that make up the whole. The American Red Cross comes late in the field where the seed has already been sown and the harvest is ready to reap, so we can do but little as compared to what has already been done but our one aim is to encourage and help with the work that has already been set on foot."

In dealing with the American organizations for war relief work, which had been in the field since 1914, Mr. Folks went on to say that it was the desire of the Red Cross to strengthen and not to alter them. He spoke of the works organized by Mrs. Wharton, Mrs. Shurtleff, the work for the war orphans, and various other organizations which had not only assisted the Red Cross by cooperation with it, but by being strengthened by the fact that the Red Cross had said to them "Go on with your good work, and let us know what your needs are and what your deficits may be, and we will supply the balance." He then drew attention to the differences in the French and American methods of organization, saying that he had observed that the French had multitudinous organizations to represent all the different kinds of war relief work, while it was the American idea to centralize all work to gain the sum total; but, whatever the differences might be, he had discovered after four months in a strange land that the result was the same and all were working for one end.

Mr. Folks then spoke of the magnitude of the refugee problem, saying that the Red Cross was most interested in the refugee families which had been found living in one small room. He mentioned one family of a husband and wife and six children living in one room and said that it was such cases that the Red Cross was most anxious to reach and

supply their needs under proper conditions, and in that way they would be fighting tuberculosis and caring for the children. The speaker dealt with other social questions and mentioned particularly the problem of relief in the devastated districts as being of great interest to the Red Cross.

Mr. W. Emerson gave a lecture upon construction and reconstruction, in which he said that the construction bureau had a wide range of duties, as it was called upon to do anything, from mending window-panes to constructing hospitals, and though it was the foundation on which many departments of the Red Cross were built, it had not the personal interest attached to it that the relief departments had. He spoke particularly of the building of huts for both civilian and military hospitals, and remarked that the hut is one of the few architectural novelties which the war has produced, and is being used for so many different purposes that in the main it has become the feature with which the construction department is most occupied. The difficulties in procuring labor have made hut building a problem which is not easy to solve. "One has no idea what the labor difficulties are now. We have had to depend almost entirely upon inexperienced civilian labor, necessarily of an inferior grade, and with trying to build in a country where we are absolutely unfamiliar with the regulations in every particular. We often find ourselves in the position of having an automobile beautifully built without being able to get the gasoline to run it. However, each difficulty overcome makes the bond stronger between us and makes us realize that we are all working for one cause."

In speaking of the labor question he went on to tell of putting up huts at an aviation camp, where the only labor to be had was that of German prisoners and pacifists; but the extraordinary combination proved a good one as the huts were put up in record time. He also spoke of the work of the "Société des Amis" and said that the Quakers are cooperating with the Red Cross. They have, so far, helped 34,000 people with their reconstruction work in the devastated districts and have built several thousand houses. Both the English and the American Quakers have combined their strength to work with the Red Cross and they are doing most splendid work.

Mr. Emerson said that the construction work of the Red Cross can be classed under ten heads: (1) The housing of the different branches of the Red Cross; (2) the building of military, civilian and children's hospitals; (3) the buildings for the housing of refugees; (4) the buildings for the canteens, which are now being coupled with (5) the rest stations that are being built in sixteen different localities; (6) the buildings for warehouses in Paris; (7) the garage buildings; (8) the recreation huts; (9) the buildings for the tuberculosis hospitals, and (10) the buildings required at Neufchâteau, which is the center for the work of the army doctors.

In the reconstruction work in the devastated districts Mr. Emerson said that the Red Cross was cooperating with the French organizations and was doing little in that line independently. In concluding his remarks he said that France had been the greatest inspiration to every country that loved Liberty.

1. The X-Rays in Phthisis.—George W. Holmes considers that while the roentgen examination of the lungs should be used perhaps much more frequently than is at present being done as a supplement to the physical examination of the chest, it should never be used as the sole means of diagnosis. An opinion based upon roentgen evidence alone is of about the same value as an opinion based upon physical findings alone. Without a careful history, both lose much of their worth; combined with other evidence, it may be of great value, as without doubt it is capable of revealing changes in the lungs which cannot be demonstrated by any other method. The lung, as seen on the roentgen plate or fluoroscopic screen, presents the following shadows: The hilus and peribronchial shadow, the linear markings, and the dark background of the alveolar structure. The hilus shadow is composed of the larger bronchi, the great vessels, lymphatic and fibrous tissue, and the peribronchial glands. The tracheal glands lie behind the shadow of the great vessels and are not visible except when they are much enlarged and calcified. They may be seen in the lateral views. The glandular shadows are distributed along the course of the bronchi, and may vary from rather fuzzy, indistinct shadows to the dense white patches of calcification. The linear markings are composed of the arteries, the bronchi, with their surrounding connective tissue, and the lymphatics and lymphoid tissue of the lungs. Changes in the linear markings are due either to changes in the tissue around the bronchi, or, as is more often the case, to changes in the lymphoid tissue. The arteries of the lungs are not subject to change. The veins are situated midway between the branches of the bronchi, and are not included in the linear shadow. A pathological process in the lung structure tends to produce changes in the lymphatics draining the infected area. Therefore, we should expect to find a shadow in the lung substance representing the site of the pathological process, and a fan-shaped area of thickened linear markings representing the course of the lymph channels draining this area. The peribronchial glands in the infected area may also show changes. All the lymph vessels of the lung tend to converge toward the hilus, excepting a small group near the periphery which drains into the pleura. Roentgen findings which are of value in making a diagnosis of tuberculosis may be divided into three distinct types—miliary, peribronchial, and parenchymal. The third is the most common type, and is seen as an insulated group of small white areas, usually near the periphery of the lung, from which spreads a fan-shaped area of thickened linear markings which extend toward the hilus. Thickened and mottled markings in the region of the bronchi may be seen; also large dense and, possibly, calcified peribronchial glands. As the process increases and these areas become larger the shadows overlap and the typical fan shape is lost. In miliary tuberculosis fine, discrete, dense spots are seen scattered evenly over the greater part of the lung field. There may also be evidences of a chronic lesion in one of both apices. These cases may show very little evidence on the physical examination, especially in children. The peribronchial type is very difficult to diagnose as far as the x-ray is concerned. Holmes in discussing the methods of examination states that the examination of the chest divides itself directly into two principal methods—fluoroscopy and radiography. The study of the chest with the fluoroscope has the advantage of being cheaper, both as to individual cost and as to equipment. It is also more easily and quickly done. The image seen upon the screen is that of the living, moving organs, and it gives data which could not be obtained from the photographic plate, such as the movements of the diaphragm, lighting up of the lung fields during respiration, the

pulsation of the different changes of the heart and possible changes in the shape of dull areas in the lungs during change of position of the patient. Its disadvantages are the inability to study carefully the detailed structure of the lungs, and the fact that it does not give us a permanent record, that is, those interested in the case must rely on the personal judgment of the radiologist, whereas, with the plate, a joint study is possible. The radiographic method has the advantage of giving an accurate, permanent record of the condition within the chest, and should show any variation from the normal which gives rise to change in density, either diminished or increased. Sufficient data may be obtained from a single plate, or it may be necessary to take plates from the front and back, upright or prone, and in a considerable percentage of cases stereoscopic plates should be taken. The number and position of the plates to be taken can usually be decided upon at the fluoroscopic observation. Without the fluoroscopic observation it is necessary to take at least three plates, two of which should be a stereoscopic pair. The ideal procedure should be a fluoroscopic observation, at which time definite records are made as to the excursion of the diaphragm, changes in shape of any abnormal shadow in reference to respiration and position, also to the illumination of the lung fields during respiration and coughing. If, at the end of this examination, the diagnosis is in doubt or it appears to be negative, stereoscopic plates with the patient in the sitting position and the tube behind, should be taken. Should the fluoroscopic findings be fairly definite, a single plate taken in the position which best shows the pathological process will be sufficient.

4. Instruction and Supervision of Expectant Mothers in New York City.—Jacob Sobel in this paper concludes the review of his work in this direction by presenting the needs of the system of instruction and supervision of expectant mothers in New York in part as follows: (1) Zoning or districting the city along lines of the baby health station service, for instruction or follow up by nurses or social workers, in the home, of mothers during the period of pregnancy, and for as long a period thereafter as necessary or possible, preferably one year. (2) Assignment by maternity institutions, whether with an in or out service, of nurses or social workers, within prescribed districts, for the instruction and supervision of expectant mothers. In the absence of such appointment, these institutions should register with the Department of Health all prospective mothers enrolled, so that the nurses of the department may give the necessary advice and instruction, in cooperation with said institutions. (3) Referring all mothers and babies discharged from maternity institutions to the baby health stations nearest their home addresses, following this with notification to the Department of Health of all babies so discharged. (4) Co-operation of all private physicians in availing themselves of the services of the nurses of the baby health stations, so that mothers under their supervision may be instructed in the hygiene of pregnancy and referred to them in the event of untoward signs and symptoms. Settlements, neighborhood guilds, churches, and day nurseries, should refer to the baby health stations all expectant mothers coming to their notice. (5) An educational campaign of instruction for expectant fathers in order to arouse them to their duty and responsibility toward the mother and the future offspring. (6) Increased interest and cooperation of philanthropic organizations and individuals in the establishment of a

prenatal service within prescribed districts and in furnishing to worthy mothers necessary material aid in the form of food, clothing, aftercare, baby outfits, and obstetrical outfits, this to supplement a large amount of such aid and relief at present afforded by the united relief agencies and charity organizations of a public and private nature. (7) A municipal or philanthropic employment organization for securing work for unemployed expectant fathers so as to reduce to the lowest possible minimum the gainful occupation of the mother before or shortly after delivery, this to act as a substitute until the possible passage of a health insurance bill, which includes maternity insurance. (8) Enactment of legislation prohibiting the employment of pregnant women in factories or manufacturing or mercantile establishments, for a period of two weeks prior to, and at least four weeks after, delivery, with provision for weekly stipends and care during this period, or, as a possible substitute, the establishment of day nurseries in or adjacent to factories, in charge of trained nurses, where mothers may nurse their babies, or where properly regulated artificial feeding can be maintained. This has been done in France, Russia and Italy; why not here? This will increase maternal nursing, decrease deaths during the first month of life, and do away, to a great extent, with the prevalent custom of leaving these infants in charge of old "mammies" and irresponsible neighbors. (9) Increased appropriation by city authorities for the appointment of an augmented corps of nurses for instruction and supervision of expectant mothers, not so much with a view to reaching all the prospective mothers—for that is well-nigh impossible—but to act as a wedge, by educational propaganda, into the inertia which now exists as to the urgency and importance of this problem. (10) Intensive studies as to the causes of still and premature births by careful analysis of the histories, examinations of the mothers, and autopsy findings on infants. (11) Provision for improved and increased obstetrical care in homes and institutions for those able to pay only a moderate fee or unable to pay at all. This presupposes greater and better outdoor maternity service, and a larger number of properly equipped maternity institutions throughout the city. If the public could be taught that such service might be obtained the midwife problem and the meddlesome accoucheur would adjust themselves, and hospitalization for delivery would become popular. (12) The application of an excessive supply of breast milk in mothers for the use of premature and delicate infants within the maternity institutions, or in the neighborhood, rather than the sale of the same for babies of the better classes, who can have other advantages, such as wet nurses, trained nurses, good surroundings, personal attention, proper clothing, etc., that money can buy, and who can better be tided over a dangerous period than those of the poor. (13) Provision for an increased number of temporary shelters, where mothers about to be delivered in institutions may place their infants and children during the period of confinement, and thus secure that peace of mind and contentment which is essential for the prospective mother. (14) The establishment at various centers throughout the city—the Department of Health, settlements, hospitals, museums, etc.—of permanent exhibits showing the various phases of prenatal and infant care. This should consist of photographs, charts, convincing statistics and literature. Periodical lectures, lantern slides, and moving pictures could be added, as indicated. In other words, prenatal care should be popularized.

7. The Venereal Disease Problem in California.—H. G. Irvine, director of the Bureau of Venereal Diseases, California State Board of Health, tells of the efforts being made in California to handle this difficult question. California was one of the first States to make an organized effort to put into effect the program proposed by the War Department and Surgeon General's Office to combat venereal diseases. It was initiated by the organization of a bureau of venereal diseases under the State Board of Health. As it is believed that the program adopted for carrying on the work is one of the most rational proposed by any State up to the present, it seems desirable at this time to publish some of the details of the work that those interested in other States may benefit. The bureau as organized has a director, two sanitarians, and a social service director. The director and sanitarians are physicians. Immediately after the organization of the bureau, the state board of health passed a regulation making all local and county health officers inspectors under the State board. This gave a very efficient state-wide organization, which at once became available to promote the work of the bureau in all communities. Copies of the program, rules and regulations will be furnished by the Bureau of Venereal Diseases, 512 Underwood Building, San Francisco. With reference to the question of prostitution Dr. Irvine says that the plan proposed by Mr. French and himself, and already in effect in San Francisco, Los Angeles, San Diego and a few smaller communities throughout the State, is as follows: All women arrested as prostitutes or vagrants are given jail sentences of from 30 to 180 days if found guilty. Before sentence is imposed, a very careful examination is made by a well trained gynecologist to see if there is clinical or microscopic evidence of gonorrhea, and a Wassermann test is made in every case. If disease is found the case is continued and the patient sent to the hospital for treatment. If no evidence of disease is found, sentence is imposed unless the woman probation officer, who has meanwhile investigated the case, recommends the woman be placed in her charge to be given work, housed, or returned to her home. In the case of women going to the hospital, they are returned to the court at once after their treatment and handled just as those not diseased, except that arrangements are made to continue their treatment as ambulatory cases when necessary. Any woman placed on probation and caught violating any rules laid down for her is summarily given a six months' jail sentence. Arrangements are also made to have mental tests given in order that proper institutional care may be recommended when necessary. Men exploiters are to be handled the same as the women. It will readily be seen that this is in no sense a plan to make prostitution safe, but rather a rational plan to withdraw permanently every prostitute possible from the market; the medical treatment is but the first step in rehabilitation. The social service work in connection with this plan is directed and coordinated by the bureau through its social service department. The medical examinations and treatment are under the local board of health. To show how this works out, Irvine quotes from a report of Judge Oppenheim, who had charge of the Women's Court in San Francisco for the month of November. Out of 156 women brought before the court, 50 have been placed on probation and are at work under the supervision of the probation officer. Thirty have returned to husbands or relatives; these also are on probation. Twenty have been returned to relatives outside the city. The other 56 are in jail or the hospital with their cases not finally disposed of. Dr. Irvine in conclusion brings out the following points: Such a bureau is perhaps the most logical organization to carry on this work. Its director should be a man specially trained in venereal disease work, he should have enthusiasm for public health work, and he should have some knowledge of administration. A social service department is an exceedingly important part of the organization. The

work should be done under the State board of health in order that it may have the authority and organization of this board at its command.

In connection with the war work it is highly important that this bureau and the work of the Fosdick commission be in closest cooperation.

1. An Estimate of the Antiscorbutic Value of Milk in Infant Feeding.—Harriette Chick, E. Margaret Hume, and Ruth F. Skelton give the results of their experiments carried out at the Lister Institute of Preventive Medicine on this work. They say that scurvy, adult, or infantile, may now be classed definitely with beriberi among the so-called deficiency diseases. Both general experience with human beings and modern experimental work upon animals have shown that these maladies arise as the result of a long period, usually several months, of imperfect nutrition. The imperfection is referred to absence or deficiency in the diet of certain unknown substances whose presence is essential for satisfactory nutrition. The anti-scurvy factor is found to be present in living, actively metabolizing tissues of plants and (to a less degree) of animals, whereas the chief sources of the anti-beriberi factor are the seeds of plants and the eggs of animals. The most valuable antiscorbutic materials we possess are green leaves (such as cabbages and salads) and fresh fruit juices; onions and the root vegetables, potatoes, carrots, swedes, etc., come next in importance; lastly, there are fresh meat and milk. The anti-scurvy vitamin suffers a spontaneous decomposition when the substances containing it are preserved by drying or any other means. This destruction takes place slowly at ordinary or low temperatures, but occurs much more rapidly at high temperatures, the rate depending on the actual temperature employed. Some loss is therefore to be expected in cooked vegetables, fruit, or milk, depending on the temperature and time of cooking. Results of their present investigation show that as regards the possession of anti-scurvy properties, milk must be classed among the less valuable materials. If reliance is to be placed upon its presence in a diet as the only means of preventing scurvy, the amounts consumed must be large, and any methods of preparation, such as heating or drying, which involve diminution of the small amount of antiscorbutic substance originally contained, must be regarded with suspicion. Their experiments also prove that fruit juices are decidedly more advantageous in overcoming scorbutic tendencies than is meat juice, and they found that the freshly expressed juices of oranges and grapes are a necessary adjunct to the diet of infants artificially fed. They further state that milk is intended for consumption in the raw condition, and seeing that cow's milk at least is endowed with no great excess of anti-scurvy vitamin, it is necessary to beware of introducing in its preparation any methods which might lead to a diminution in this valuable constituent. Such processes include the heating (pasteurization or boiling) of milk, adopted of necessity to afford protection from milk-borne disease, and the drying of milk which, in addition, has the great virtue of economy. Experiments on guinea pigs show an almost complete loss of antiscorbutic properties to have taken place in both dried and strongly heated (120 deg. C. for one hour) milk. In practice, where milk is heated to a less degree—e.g. "pasteurized" or boiled—loss in its vitamin value is also to be apprehended. When any of these methods

are employed in preparing cow's milk for infants it is therefore necessary that the diet should be reinforced with an extra supply of antiscorbutic material from outside. At the present time the regular use of fresh orange juice or fresh grape juice in the infants' dietary may present some difficulty owing to the restrictions placed upon the importation of fresh fruit by war conditions. These fruits are likely to be scarce during the coming winter, and out of the reach of poor households. These investigators are, therefore, at present engaged in determining the antiscorbutic value of raw juices expressed from various root vegetables which are home grown and plentiful, in the hope of discovering a satisfactory and cheap substitute for these fruits. Some encouragement for this line of research already exists in the clinical data available as to the distinct value of potatoes, even when cooked, for the cure of infantile scurvy. The writers summarize their findings as follows: (1) Raw cow's milk contains the accessory food factor (vitamin) which protects from scurvy, but this is present in small amounts and is further diminished by heating or drying. (2) Infants fed on heated or dried milk, or on any milk substitute, should receive also some antiscorbutic ration, such as fresh fruit juice or potato. It is probable that the raw juices of turnips and swedes can also be employed.

5. A Method of Skin Grafting Under Septic Conditions.—Paul Bousfield, resident surgeon, American Women's Hospital for Officers, London, offers a method by which he has been able to obtain successful grafts upon areas which, though "clean" to the naked eye, were still actually suppurating, dressings which had been left on for twenty-four hours showing a certain amount of pus, and even possessing an offensive odor. The following case illustrates the method in question: The patient had been wounded in the arm, the head, the back, and the left thigh. The wound in the arm had necessitated a guillotine amputation in France, which had remained septic; the wound in the thigh had been excised in France, and when he received the patient in England it consisted of an area on the posterior surface extending from 2 inches above the knee to the natal fold. The outer border reached to about 1½ inches in front of the great trochanter, and the inner border to within about 1¼ inches of the rectum—an area of approximately 72 square inches, in which all the skin, superficial fascia, and fat had been removed and had left the hamstring muscles exposed and still in a septic condition in very nearly their whole length. On first viewing this leg it seemed doubtful whether it could be saved, especially as the wound was of such an irregular shape that a plastic operation by means of which parallel strips of skin might be brought over portions of the exposed surface was not possible. For ten days the wound was dressed on every third day with pure sterilized liquid paraffin containing 1 drachm of ordinary bipp to the ounce. At the end of this period the wound was quite clean at the edges and had granulated well over the muscles; a skin graft under the following conditions was decided upon in spite of the fact that the dressings were still somewhat offensive. The edges of the wound and the skin of the buttocks, whence the graft was to be taken, were sterilized with iodine; the surface of the wound itself was sprayed with zoel, which the manufacturers made by mixing 1 pound of 78 per cent. electrolytic caustic soda ground to pass through a sieve with ten holes to the linear inch, with 1½ pounds of No. 20 pure salt; to this is added 5¼ pounds of granu-

lated borax and the whole well shaken together. Combination of the caustic soda with the borax takes place rapidly, resulting in a mixture (zoel) containing 19½ per cent. sodium chloride, 3 to 4 per cent. of sodium diborate, and 76½ to 77½ per cent. of sodium monoborate. He then raised small portions of the skin of the buttocks with forceps and dissected off portions about a quarter of an inch in diameter and one-sixteenth of an inch thick in the center. He passed a single stitch through each graft and through the granulation tissue, suturing each graft in careful apposition; in all he planted about thirty-five grafts in this way. Again he sprayed with an atomizer a solution of zoel upon the grafted wound, and then dressed the whole with gauze soaked in sterilized paraffin, so that the dressing should not dry and tear off the grafts or cause bleeding when it was changed. The paraffin dressing was left on for forty-eight hours without removal, but was moistened from time to time with fresh paraffin in order to prevent it from sticking. At this period the dressing had begun to smell, and the edges of the dressing had become green. He therefore redressed the wound, and sprayed it again with a 2 per cent. solution of zoel, afterwards again placing over the surface gauze soaked in paraffin. This procedure he repeated from time to time on the average every twenty-four hours, and at the end of twelve days every graft had not only taken but had spread to more than twice its original area. Bousfield states that he has used this method on other cases, and the success of the technique he ascribes to three outstanding conditions: (1) The fixing by means of sutures of the grafts, so that, although in an awkward position, they cannot be removed when the wound is dressed. (2) The use of liquid paraffin as a medium for the dressing, which prevents any adhesion, and hence movement of the grafts. (3) The use of an antiseptic spray which is efficient in its germicidal powers, and yet non-irritant and non-poisonous to such delicate tissues as skin grafts; this last is, without doubt, the most important of the three.

6. A Note on Skin Grafting.—Norman H. Joy offers the following points to be attended to in skin grafting: (1) The raw surface must be in a good condition for skin grafting—that is, it must be covered with healthy granulations and as free as possible from discharge. If there is much discharge many pieces of grafted skin are raised and so fail to “take.” To prevent this the wound should be dressed with 1 in 1,000 flavine for four to seven days before operation. In the cases he has treated by this method there has been no discharge between the grafts, although he regarded them as very unsuitable cases before the application of flavine. (2) The grafts should not be covered with any dressing, and should be properly protected. At the suggestion of another surgeon, Joy has used inverted boxes of various sizes and shapes, cut to fit the contour of a limb, if necessary. The edges of the box should be slightly padded, and the box should be amply large, so that there is no risk of the padding touching the wound. (3) The technique used is as follows: The surface from which the skin is to be taken is prepared in the usual way. The wound is covered with a simple gauze dressing, and when this is removed care is taken to disturb the surface as little as possible. Two razors are employed, so that one can be dipped into boiling water, while the other is being used; thus the freshly cut surface heals without any suppuration. The grafts are cut about the size of a postage stamp, and with practice can be cut to almost any shape. The skin and razor are kept thoroughly wet with normal saline, so that the grafts can be more easily cut and removed from the razor. The grafts are generally placed about ¼ inch apart, but can be placed closer in a very clean wound. The box, sterilized, is adjusted and fastened down by long strips of rubber plaster; the ends of these are thoroughly bandaged, the bandage being brought up to the box as close as possible on all sides, but not over it, and it is always used in the form of a spica whenever possible. It is then pinned to the box with a liberal supply of safety pins. The box remains in position for several days, when it can be removed. The grafts are then found to be firmly fixed, and any dressing, such as fomentations or red lotion, can be applied.

Berliner klinische Wochenschrift.

The Relations Between the Endocrine System and the Constitution.—C. Hart confines his remarks to theoretical considerations of the influence of the glands of internal secretion on the formation of somatic characters. He points out the great complexity of changes arising in these systems which react upon each other. The writer prefers the theory of adaptation of the organism to a new condition of circumstances, rather than that of antagonism and compensation. What is just now most wanting in science is the knowledge of primary, fundamental part played by each endocrine gland in particular. But this research is rendered difficult on account of the correlation of the physiological actions, perhaps also from the plurality of the functions of the organs studied (suprarenals, hypophysis, for example). In this same order of ideas the writer does throw some light and precision on the question. Thus the thymus is essentially an organ of the bodily development and growth, as has been demonstrated by experiments carried out on tadpoles by the administration of thymus tissue. In the evolution of the thymus the reproductive functions take precedence over that of growth, and here again the dependence of the endocrine system is evident. Hart fed tadpoles with thyroid gland; their growth was inhibited and their metamorphosis accelerated. The same was found for regeneration; the thyroid feeding caused it to be very rapid, but insufficient, while thymus feeding caused it to become exuberant. The thyroid should therefore be considered as an organ of differentiation, and Hart has succeeded in transforming an axolote into an animal very closely resembling the salamander by exclusive thyroid feeding. Now it was already known that the axolote is a larval form of the latter family. Hart looks upon this “neotenia” (persistence of the juvenile state) as quite similar to infantilism in man. Finally, the writer asks the question regarding the influence on these processes of development from exogenous factors, such as climate, intoxications, etc.

Intravenous Injections of Iodine in Syphilis and the Relationship of Iodine to the Blood Formula and Pressure.—Engwer concludes as follows: No specific change is noted, either from the viewpoint of the blood formula or pressure. Pregnancy is a contraindication to intravenous exhibition of iodine.

Münchener medizinische Wochenschrift.

November 6, 1917.

The Transplantation of Tissues from the Monkey and the Ultimate Results.—H. Küttner reports some cases of bone transplantation from monkey to man. As might be supposed from the humoral relationship which has been established by Uhlenhuth, Wassermann, and others, this procedure resorted to by Küttner may result in permanent success, and he has resorted to it for four to five years. The advantage of the method resides in the fact that one can thus utilize fresh bone tissue, it being removed from the animal at the time of the operation. An autopsy of the monkey done at the same time will reveal any morbid process which might contraindicate the use of the bone in the human subject. Küttner expects to obtain great results from vascular and tendon transplantation from the monkey but he is more skeptical regarding the utilization of nervous tissue.

Menstrual Epistaxis and Organotherapy.—H. Bab, in his first paper, in the first place recalls the facts already established by recent researches on the question of ovulation (eighteenth day), and the inhibitory action exercised by the corpus luteum on menstruation. Bab next shows the barrier set up against the normal menstrual flow by a hyperplastic or otherwise pathological uterus. In these circumstances menstrual epistaxis assumes a compensative rôle. The localization of the deviation in the nasal mucosa is explained by the physiogenetic and functional relations which unite olfaction with the genital sphere. The writer develops his reasoning by resorting to numerous physiological and clinical arguments which are too long to cite, but mention may be made of the fact reported by Fliess, namely, that dysmenorrhea can be relieved by the application of a solution of cocaine to the nasal mucosa.

Deutsche medizinische Wochenschrift.

November 8, 1917.

The Relationship Between Recurrent Fever and "Five Day" or Volhynia Fever.—J. Koch desires to include in a single clinical picture recurrent fever, Volhynia fever, and the bilious typhoid fever of Griesinger. All three morbid processes, he says, are caused by Obermeier's spirillum, and although this fact has not been recognized sooner in the case of Volhynia fever, in spite of the great analogy in the clinical phenomena, this is simply due to the fact that the organism is in very small number. Volhynia fever is caused by a spirillum which is an involution form of the recurrent fever organism. Koch, in order to give ground to this opinion, produces microphotographs and offers the following arguments: (1) This organism is found in recurrent fever as well as Obermeier's organism, in the phase of the process when the serum has reacted against the infection, and also even after treatment with salvarsan. (2) Every degree in the evolution from one organism to the other can be followed. (3) The spirilla undergoing regressive changes that have been found by Koch in Volhynia fever are motile when examined in the hanging drop. The identity of the two morbid processes is still further demonstrated by the simultaneousness of their apparition in epidemics at the Oriental front. As to Griesinger's bilious typhoid, it is merely a septic form of recurrent fever, characterized by the icterus gravis which accompanies it. Here again the spirillum of Obermeier may be present in considerable masses in the blood, as is shown by the microphotographs taken by Koch.

The Development of Variolic Epitheliosis on the Vaccinated Cornea of Rabbits.—According to G. Paul, corneal vaccination produces first a proliferation and then a degeneration of the infected epithelial cells. These phenomena offer very distinctly the characters of a defensive reaction. After the results of a histological study of these changes Paul comes to the conclusion that the causal agent of variola is a parasite which becomes exclusively localized in the epithelium and that no histological changes take place in the connective tissue.

Wiener medizinische Wochenschrift.

November 10, 1917.

Ammon's Horn and Epilepsy.—L. Efinger proposes to explain the very frequent existence of epilepsy, in which there is sclerosis of Ammon's horn, as follows: During labor laceration of the tentorium of the brain occurs, and if the child survives a sclerous process takes place in the region of Ammon's horn. This cicatricial predisposes the subject to the development of epilepsy.

Clinical Researches on the Phenomena of Spasmodicity.—S. Eben believes that spastic reflexes are governed by the sudden elongation of a muscle beyond its normal length. This rule admits of no exception, excepting in the case of the extensors of the forearm and leg; this is because flexion causes the muscles to become closely applied to the articular pivot, a fact which prevents the transmission of the shock to the entire muscle. Besides this, the suppression of the contractures by Esmarch's bandage acts in quite the same way, by compressing the muscle and preventing it from being subjected to the shock. The contractured muscles which are not compressed by the elastic band do not undergo any variation in the degree of their contracture. The anemia resulting from the application of the elastic band plays no part in the process.

Medullary Commotion.—J. Bauer insists on the difficulty of separating the disturbances due to anatomical lesions from those resulting from pathological lesions which offer no structural change. It is quite impossible to affirm that such or such a case is purely the result of shock. Bauer reports several different cases, and discusses the organic or the functional nature of the lesions presented by each patient.

Cerebral Metastases from a Primary Melanosarcoma of a Labium Majus.—Kotzareff reports a case of this

rare sequence in which metastases occurred by both the blood and lymph routes and intracranial metastases were present. In the lymphatics the infection traveled from the vulva to the groins along the homolateral (left) side and extended along the vertebral column until it reached the left hemisphere. Locally the growth involved much of the external genitals. In general these growths originate either from a pigmental nevus or in the sound skin and are invariably single at the outset and are highly malignant, not only in rapid spread but in invariably recurring after removal. The malignancy appears most strikingly, however, in early, generalized metastases. The latter not only invade the lymphnodes, group by group, so that, as in the author's case they can reach the most distant localities, but also through the bloodvessels attack the viscera and skin. In detail the author's case was as follows: The woman was 56 years old (menopause at 49). Her sexual life had been normal (two living healthy children and a single miscarriage). Six months before she had noticed the small nodule in the left labium majus. The neoplasm continued to grow and became pedunculated, also bleeding easily. An inguinal metastases the size of a hen's egg soon followed and its growth was painful. The patient was much more anxious about the secondary than the primary growth and sought treatment for it. Upon examination she was seen to have a number of nevi, including several on the vulva. A number of biopsies placed beyond doubt the diagnosis of melanosarcoma. Just as it was decided to operate a bone metastasis was discovered at the height of the first dorsal vertebra. This growth, in fact, was readily palpable from without, while at the same time able to cause some pressure paralysis. Another metastasis, higher up, caused pressure upon the radicles of the brachial plexus. The local growth on the vulva by its hemorrhagic character caused notable anemia and was ligated off. Radium for the inguinal mass was refused. Later there was intracranial mischief—the Wernicki type of aphasia with slight hemiplegia, word blindness and word deafness suggesting metastases in certain nerve centers. Patient died in coma from the intracranial disturbances. Autopsy revealed extensive metastases. Small growths were present in the left pleura. A focus of softening lay athwart the left fissure of Sylvius, compressing Broca's speech center, while a second was present in the left occipital lobe. The chief metastases would therefore be classed as pulmonary, vertebral, and intracranial. There was absence of uniformity as to coloration, some being black, others white, others, again, mixed. The metastases all occurred on the left side of the body, which fact is explained by the author by lymphatic propagation. He states, however, that blood metastases were also present, and appears to infer that the intracranial foci were of this origin. This point is left undecided. The pleural metastases seem to have been referred to lymphatic infection, although this is also a moot question.

The Reaction of the Local Tubercle.—Stating in the September number of the *American Review of Tuberculosis* that therapeutic agents for tuberculosis should be considered from two points of view: (1) as direct therapeutic agents or those that directly influence the bacilli themselves, and, (2) as indirect therapeutic agents or those that influence the host and thus indirectly act upon the bacilli, Corper of Chicago reports the study of the effect that various bacterial and chemical substances may have on the ability of the tissues to react with specific and nonspecific tubercle. Guinea-pigs that have received a preliminary subcutaneous injection of dead or living tubercle bacilli react more vigorously to a subsequent intracutaneous injection of dead tubercle bacilli than do normal animals. They do not undergo such change in reaction to kaolin or calcium carbonate, given intracutaneously, nor to splenic tissue, aleuronat or edestin. Guinea-pigs, previously injected with typhoid and pseudodiphtheria bacilli reveal slight, if any difference in reaction to the intracutaneous injection of tubercle bacilli from that seen in normal animals. Starvation of guinea-pigs that have had previous injections of dead tubercle bacilli tends to lower their reacting power to subsequent intracutaneous injections of the same.

Book Reviews.

THE BATTLE WITH TUBERCULOSIS AND HOW TO WIN IT;
A Book for the Patient and His Friends. By D.
MACDOUGALL KING, M.B. Price, \$1.50. Philadelphia:
J. B. Lippincott Company, 1917.

THE author of this volume has sojourned for nearly four years in America, of which he spent a year and a half in sanatoria in Canada and the United States and the rest in health resorts. The book he has written is the result of his personal experience with the disease with which he has been himself afflicted. All the chapters have decidedly timely headings. In Part I the titles of the fourteen chapters are the following: The Enemy; The Defence Forces; The Skirmish at the Outposts; The Promise of Victory; Reverses; Days of Peace; Strengthening the Home Forces; War Clouds; The Intelligence Department; The Chief Medical Officer; Choosing the Battle Ground; Campaigning; The Orders of the Day. The second portion has equally martial names for the chapters, such as "Commandeering the Home," "Tactics of the Enemy," "The End of the Battle," "The Spoils of War," etc.

Although the author has made an attempt to bring his medical phraseology down to the understanding of the common people, he has not always succeeded in this. Thus, for example, there are two illustrations copied from Crile's "A Mechanistic View of War and Peace" and intended to show the effect of extreme emotion, which have for legend the words "A section of a normal cerebellum," and "Section of cerebellum showing effect of extreme emotion (fright)." If the book is intended only for the well-educated consumptive this is all very well; otherwise we question the wisdom of using such illustrations or such words as "normal cerebellum," "mechanistic view," etc.

Some of the advice the author gives is unusually good, but he himself admits the difficulty of carrying it out. He says: "Your mind should be as your body—not riveted to any one point, but so dreamily relaxed that if any one were to ask you 'What are you thinking about?' you would be unable to tell him." If we could free all our consumptive poor from mental anxiety, the thorough relaxation of mind and body would be an easy thing. Attention should be called to an interesting discussion on the help which the consumptive may derive from religion, where the author says, among other things, "More things are wrought by prayer than this world dreams of," and where he quotes the words of Professor William James: "The sovereign cure for worry is religious faith."

In the appendix there are given some instructions regarding the disposal of the sputum. There is nothing new among them and some of the directions are far from practical. How many patients in a tenement house who accidentally or carelessly spit on the floor would carry out the following instruction: "A 2 per cent. solution of either lysol or chlorinated lime should be poured on the area of floor contaminated, and allowed to soak for at least an hour before being wiped up." An injunction to scrub the "area of floor contaminated" thoroughly with hot soap-water would be carried out more readily.

The book contains many personal reminiscences of the author's sojourn in the sanatoria, and gives a number of illustrations showing groups of patients with whom he has associated. As a guide for the average tuberculous patient this book of 258 pages, although reasonable in price, is too voluminous and too scientific. As a volume to be added to the patients' library in a sanatorium where the intellectual class predominates it will prove interesting reading matter.

A HANDBOOK ON ANTISEPTICS. By HENRY DRYSDALE DAKIN, D.Sc., F.I.C., F.R.S., and EDWARD KELLOGG DUNHAM, M.D., Emeritus Professor of Pathology, University and Bellevue Hospital Medical College; Major, Medical Officers Reserve Corps, U. S. Army. Price, \$1.25. New York: The Macmillan Co., 1917.

THIS little book gives a concise account of the principal chemical antiseptics which have been found useful for surgical purposes during the present war. Information has been collected from various sources and put in convenient form, so that the proven facts and accepted theories may be easily available for the men

who are soon to be engaged in the care of the wounded. No attempt has been made to cover all antiseptics that have ever been used, but attention has been paid to those only which have received at least some measure of endorsement from military surgeons during the past three years. The methods of preparation and use of a multitude of antiseptics, plain and in various combinations and mixtures (in liquids, oils, or pastes), are concisely detailed. There are a number of tables showing the relative germicidal values of various well known as well as the comparatively new antiseptic agents. The potency of some and the almost utter uselessness of others are well shown. For example, the bacterial count of a medium infected with *Staphylococcus aureus* and acted upon by a solution of hydrogen peroxide decreased for the first five minutes, but increased rapidly thereafter and at the end of six hours was practically the same as before the test. The newer antiseptics, such as Dakin's solution, chloramine-T, dichloramine-T, and brilliant green, as well as the phenol group, iodine, etc., are adequately covered.

The book is not concerned with surgical details but gives all necessary information regarding the preparation and uses of the antiseptics themselves. For this it is a most valuable aid to the surgeon.

THE CAUSATION OF SEX IN MAN. A New Theory of Sex Based on Clinical Materials, Together with Chapters on Forecasting or Predicting the Sex of the Unborn Child and on the Determination or Production of Either Sex at Will. By E. RUMLEY DAWSON, L.R.C.P., London; M.R.C.S., England, etc. Price, \$3.00. New York: Paul B. Hoeber, 1917.

THE second edition of Dr Dawson's book contains considerable new evidence as to the correctness of his theory, which in brief is that the sex of the child depends on the ovary and on one particular ovary, the organ of the right side being termed by the author the male ovary. As far as the reviewer is aware, Dawson's theory has not been indorsed by those whose opinions carry weight, although his colleagues regard him as a conscientious and zealous worker and admit that he has been unusually successful in his forecasts. Doncaster, commenting on the theory (1914), states that it is of no value for certain mammals nor heterologous male twins; while the exceptions seen after unilateral ovariectomy are far too numerous to be explained by residual ovarian tissue. The arts of forecasting and determining sex seem as complicated as the theory itself is simple and necessitate the supposition that male and female ova are discharged during alternate months—something extremely difficult to prove. The author trusts that the immediate demand for a preponderance of male births will lead to the general use of his method, and as the latter is not in any way burdensome it is to be hoped that his wish will be gratified.

KIRKE'S HANDBOOK OF PHYSIOLOGY. Revised and Rewritten by CHARLES WILSON GREENE, A.M., Ph.D., Professor of Physiology and Pharmacology, University of Missouri. Ninth American Edition. With Five Hundred and Nine Illustrations, Including Many in Colors. Price, \$3.75. New York: William Wood and Company, 1917.

A BOOK that reaches its ninth edition needs very little in the way of recommendation; such a record speaks for itself. We have always regarded Kirke's Handbook of Physiology as one of the old, reliable textbooks which has continually kept pace with the onward march of this all-important science. The present edition is no exception and contains some important revisions, particularly in the chapter on the subject of Nutrition. Professor Greene connotes the recent work of Osborne and Mendel in this country on food requirements during growth, and that of Voegtlin, Funk and others on vitamins in their relation to the deficiency diseases. There is also included a section on the influence of the diseases of the ductless glands on metabolism, a topic which is in keeping with the close association that now exists between physiology and clinical medicine. Throughout, the book is well up to the high standard maintained in previous editions. The illustrations are abundant and well selected. The print is good and the size of the volume makes it convenient for ready reference.

*Thirtieth Annual Session, Held at St. Augustine, Fla.,
December 18, 19 and 20, 1917.*

THE PRESIDENT, DR. WILLIAM D. HAGGARD, NASHVILLE,
TENN., IN THE CHAIR.

A Brief Résumé of the Causes and Treatment of Rupture of the Uterus During Labor.—Dr. E. GUSTAV ZINKE of Cincinnati said that the most frequent cause of rupture of the uterus was a prolonged second stage of labor, due to an obstruction of either maternal or fetal origin. The appearance of the contraction ring was the most significant sign of an impending rupture of the uterus. When rupture of the uterus was not the result of an imperfectly united cesarean scar, extirpated tube, myomectomy, etc., but was solely the consequence of an obstruction, its clinical picture was clear and definite. The symptoms were easy of recognition, and the rupture might be anticipated and promptly diagnosed if the attendant was upon the scene at the time. The management of rupture of the uterus during parturition differed according to the completeness or incompleteness of the rupture, the amount of hemorrhage, the condition of the mother, and also according to whether the patient was in a hospital or at home. If the rupture was incomplete, the child might be extracted per vaginam provided the hemorrhage was not severe and the patient was in her home; if the patient was in a hospital, an abdominal section, quickly performed, might save both lives even if the loss of blood had been great. If the rupture was complete, and the child was alive and vigorous, an immediate abdominal section was indicated, no matter what the condition of the mother, or whether she was at home or at a hospital. If the child was dead and the mother's condition was hopeless, it was of no avail to interfere surgically under any circumstances. If the child was dead and the mother's condition fairly promising, the child should be at once delivered through the abdomen, and the rent in the uterus and peritoneum repaired; or, if an infection existed, a hysterectomy should be performed. It was understood that this latter treatment promised little for the mother when it must be carried out at home; but that her life might often be saved if the operation was performed in a hospital.

Report of Eighteen Cases of Cesarean Section Done with Local Anesthesia.—Dr. HUGH H. TROUT of Roanoke, Va., thought it was interesting that while an increasing number of operations were being done under local anesthesia, cesarean sections, except in few instances, were not being done by this method. There was very little pain to the operation, only when the uterus was lifted out of the peritoneal cavity, and there was no pain on incision of the uterus. The eighteen cases proved Lenander's contention relative to the sensibility of the various viscera and parietal peritoneum. So often where cesarean section was indicated, a general anesthesia was contraindicated, chiefly in eclampsia, when local anesthesia was almost ideal. He introduced sutures into the uterus before incision was made into the same, and then, after the incision, these sutures were tied across the incision so as to give double locking mattress sutures which not only approximated the surfaces, but controlled the hemorrhage at the same time. The three maternal deaths in eighteen cases were all with eclampsia, and in all three delivery had been attempted with forceps before the operation. He felt where the condition of the mother made the giving of a general anesthetic unsafe, the employment of novocaine was indicated, and its use did not present the difficulties one would naturally expect.

Dr. I. S. STONE of Washington, D. C., said that if there was a rupture of the uterus we might, in the first place, hesitate as to the propriety of interference if the rupture was in the lower third. But the question arose, was the hemorrhage persisting or had it ceased? If it had ceased one would sometimes hesitate to perform an operation through the lower route. On the other hand, if the uterus was ruptured above, how could one hesitate very often in deciding to deliver by

forceps, by traction, or by version? The tendency at the present time was in favor of abdominal cesarean section. Having decided that there was rupture of the uterus and the hemorrhage was likely to proceed, one should go right after the source of the rupture and hemorrhage. Probably one would under all circumstances go after the hemorrhage at its origin and deliver unless the child was so far in the second stage as to make it necessary to deliver below because it was impossible to do so from above.

Dr. F. W. PARHAM, New Orleans, was very glad Dr. Trout had been so successful in his 18 cesarean sections. He was surprised to hear him say that in the last three cases he had found the absence of adrenalin of no consequence; that the anesthesia was as good without as with the adrenalin. This might be explained by the fact that cesarean section was a comparatively short operation so that the effect of the adrenalin did not pass off. Brown in his book on local anesthesia called attention to the fact that the addition of adrenalin enabled the surgeon to substitute novocaine for cocaine. He had had some trouble in getting novocaine in New Orleans and had recently been employing apothesis with satisfactory results. It was less toxic in its effect than novocaine and was absolutely as anesthetic so far as his observation and experience went. He had not seen any untoward effects from the use of apothesis.

Dr. JOHN WESLEY LONG of Greensboro, N. C., said that, several years ago, when he investigated very thoroughly the literature of cases of rupture of the uterus, the most surprising thing to him was that the rupture began from the peritoneal side rather than from the mucosa side. This was evident by the autopsy findings in cases of rupture of the uterus, and there were other ruptures found than the one that went clear through the uterine cavity, going through the peritoneum and partially through the muscularis. At that time, in a paper he read before the Washington Obstetrical and Surgical Society, he reported the only case of rupture of the uterus that had ever come into his hands. The patient was an old primipara, who was under the care of competent general practitioners; following a very severe pain (it was a vertex presentation) the fetal head had not descended, and on examination they could not find the uterus in the pelvic portion, so one of the practitioners introduced his hand through what proved to be a rent, took hold of the feet of the fetus, the fetus having escaped into the abdominal cavity, and delivered the baby in that way. He saw the patient about four hours after the delivery. She was removed 16 miles to the hospital, and 12 hours after the accident he opened the abdomen and did a supravaginal hysterectomy. The rupture occurred in front of the uterine artery so that there was very little hemorrhage. The woman made an uneventful recovery.

Dr. J. M. MASON of Birmingham, Ala., said that while it was a matter of discussion as to whether puerperal eclampsia in a woman who had not yet gone into labor should be treated by expectant methods or by cesarean section, he was of the opinion that cesarean section was the proper procedure in these cases. The great danger had been not so much the operation, which was perhaps not as shocking in many instances as prolonged labor, but the superadded general anesthetic which had heretofore been used in cesarean section. Local anesthesia removed the serious drawbacks to cesarean section.

Dr. HERBERT P. COLE of Mobile, Ala., expressed himself as being a firm believer in local anesthesia. Several years ago at Cincinnati he reported 700 cases of laparotomy done under local anesthesia. One of the patients was an 18-year-old girl from whom he removed a 40-pound ovarian cyst. Since then he had performed hysterectomies under local anesthesia. He had also removed a 14-pound myoma from a woman, 60 years of age, with a bad heart lesion, under local anesthesia without particular discomfort.

Dr. CHARLES R. ROBINS of Richmond, Va., said all were familiar with the fact that at the end of labor the veins were enormously distended and extremely tortuous, and he believed that in the vast majority of cases, where there was a fatal hemorrhage from rupture of the uterus, it was from the venous plexus and not from

the uterine artery. If there was an injury to the venous plexus, the veins being as large as the little finger, the bleeding was continuous and there was no effort at spontaneous stoppage. He believed that was the reason why we could always open the abdomen in preference to trying to complete the operation from below.

Dr. Zinke, in closing the discussion on his part, said it was not quite clear to him why we should resort to local anesthesia to perform a cesarean section when the other anesthetics, like chloroform and ether or the A. C. E. mixture, had been so satisfactory. It saved the woman the shock that she necessarily experienced when she witnessed the operation. There was no place for surgery in the treatment of puerperal eclampsia, and it had not added one iota to the reduction of the maternal mortality of eclampsia. Cesarean section, which was not formerly advocated for placenta previa, was now recognized as the proper procedure, and the speaker advocated it more than he had fifteen years ago.

Dr. TROUT, in closing, asserted that patients with eclampsia had not done so well in his experience under general anesthesia as they had under local anesthesia.

Cranial Decompression for Head Injuries Accompanied by Signs of Increased Intracranial Pressure.—Dr. R. L. PAYNE, JR. of Norfolk, Va., reported 29 consecutive cases of severe head injuries accompanied by marked increase in pressure in which subtemporal decompression was done in every case; 22, or 75.86 per cent., of these cases recovered, while 7, or 24.14 per cent., died. In the last 7 successive cases chosen for operation there was only one death following decompression. He divided head injuries into two types, mild and severe. The mild cases recovered without ever developing high increase of intracranial pressure. It was only in the severe types of head injuries accompanied by a marked increase of pressure that decompression should be considered. The indications for decompression in these severe head injuries depended on the four cardinal signs found from study of the pulse rate, the eye grounds, the spinal pressure, and the systemic blood pressure. With reference to contraindications for operations, he had never seen a case of acute high intracranial pressure with a pulse of 45 to 50 recover by operation if the case was left unoperated upon until the pulse on the secondary rise had reached 95. Results would be much better in these cases if, with the proper indications present, we would help to relieve the threatened danger to the medulla and the rest of the brain by a cranial decompression.

Arthrodesis and Bone Graft in Reconstruction Surgery.—Dr. F. G. DUBOSE of Selma, Ala., said that as a part of the general preparedness propaganda, he would ask the surgeons in civil practice to begin a more systematic and enthusiastic effort, advising operations where any cripple would be made better fit to do his little bit. Patience and persistence were necessary. He would call attention to the absence of quick and dramatic cures which were so attractive in other surgical endeavors, as compared with the tediousness and extent of time required before results and efficiency were obtained in orthopedic surgery. He would also emphasize that simplicity in armamentarium was easily obtainable by seeking the aid of blacksmiths and mechanics, and with the expenditure of some mechanical ingenuity on the part of the surgeon. He wished to exhibit a fixation frame model which permitted the patient to be securely immobilized at any part of the trunk, and extension and counterextension made on any of the extremities without risk of subsequent misplacement of the adjusted or apposed fractures or arthrodesed joints. A plea was made for the institution of operative relief before such destruction of the bony framework of joints had occurred which removed material essential for good results following arthrodesis. Attention was called to the rôle played by focal infections as an etiological factor and as a source of complications following bone and joint surgery; a thing to be sought for and removed before or at the time of operation. Stress was laid on the preliminary preparation of the patient, elimination, supportive, and vaccine or serum treatment. Lane's fanatically aseptic, knife and fork, technique was commended, and its adoption urged as essential to prevent loss of life and failure in obtaining results. The hypochlorite of soda solution saturation of

infected wounds, especially of bones and joints after the Carrel-Dakin method, was endorsed as the quickest means of obtaining fields fit for clean operative work, which were infected when presented for surgery. Murphy's formalin-glycerin injection in closed septic joints for removing the infection and preparing the joint for early operation had been repeatedly tried out by him with satisfactory results. Illustrative cases of arthrodiesis of hip, knee, and elbow ankylosis, bone graft in osteitis cystica fibrosa, and Pott's disease were reported.

A Specific for Every Pathogenic Microorganism.—Dr. EDWARD H. OCHSNER of Chicago said that the idea of a specific in medicine was not so very new, as both homeopathic and eclectic medicine were built up, at least in part, on this theory. The application of the theory in those instances was, however, premature as the etiology of disease was not sufficiently understood at that time. Today with our more accurate knowledge of infections, the theory was not only sound, but its application in these conditions was feasible. Every wild beast had its deadly enemy; every plant its parasite, and every parasite its parasiticide; and almost every known chemical poison had its chemical antagonist and probably also its physiological antidote. If the above statement was true, it should be possible to find a specific for every pathogenic microorganism which should not be harmful to the human host, but when we consider the different species of pathogenic microorganisms it was not likely that we would ever find a universal germicide. He took up the different pathogenic bacteria, such as the gas bacillus, colon bacillus, gonococcus, *Spirocheta pallida*, surgical tuberculosis, tetanus, etc., and discussed the remedies that had been found most effective by other surgeons as well as himself in the treatment of these various infections. In actinomycosis, removing the foci of the infection, such as diseased tonsils, teeth, beards of barley or chaff of grain, then laying open the sinuses to the very tips and giving the patient sixty grains of potassium iodide for three days, followed by an interval of four days, and then repeating, as first suggested by veterinarians in the treatment of lumpy jaw in cattle, had resulted in the cure of every case which he had under treatment. It was quite essential that all the above things be done carefully and conscientiously. He had seen a number of cases in which one or the other of the above directions were neglected. The disease persisted for months and was relieved only when they were all systematically employed. Giving the potassium iodide in large doses followed by an interval of suspension of the drug seemed quite an important item in securing prompt and permanent relief. In regard to the merits of Dakin's solution, he said that while in certain forms of saprophytic infection Dakin's solution might be of value, he considered it useless in some of the infections and even positively harmful in others.

Fracture of the Long Bones: A Clinical Study.—Dr. FRANCIS REDER of St. Louis, Mo., chronicled the clinical deductions gleaned from the case of a young woman, 24 years of age, who sustained a simple oblique fracture of the left femur about three inches below the great trochanter, and a compound fracture of the left tibia and fibula. The mandible at both angles was also fractured. From the treatment employed the patient at the present time was able to stand erect and was making satisfactory progress in walking. Mental fatigue and joint pains necessitated that the exercises be of short duration. The long confinement caused ligamentous relaxation in nearly all the joints of her body. This was exemplified in the frequent subluxations of her shoulder joints by some trivial movement. In summarizing it might be said that the dominant facts in this case were: the successful bone grafting 16 and 19 months respectively after the fractures had been incurred; the successful bone grafting following a septic process; the successful bone grafting after non-union following resection of the bone ends; excision of three inches from the femoral shaft, without causing any apparent damage to the mechanism of the thigh muscles; the violent and long continued muscular contractions; failure to anticipate these muscular contractions; failure to judge the violence of these contractions; failure properly to secure the bone ends of the left femur after excision; failure properly to immobilize the extremities from the start; the successful mould-

ing of the callus of the left femur four months after excision. The length of time it required for the consolidation of the callus to permit weight bearing, and the promptness with which the patient was able to discontinue the morphine.

Traumatic Rupture of the Spleen.—Dr. A. MURAT WILLIS of Richmond, Va., said that subcutaneous traumatic rupture of the spleen was unusual without other serious injuries, and especially was this true if the spleen was not markedly enlarged or unduly movable. The four cases he reported in his paper occurred in his service in a period of approximately three years. In summing up the histories of these four cases, he found that all presented the following points in common: All were males; blow on left side of body in splenic region; secondary anemia and leucocytosis; no external evidence of injury about the body; rigidity and tenderness of the abdomen; all had shock following splenectomy. All the spleens were practically normal in size with short pedicles and without any history of previous disease of the organ. Three out of the four patients had agonizing pain in the left shoulder, which was promptly relieved by splenectomy. The fourth case was that of a child sent in for concussion of the brain, and as he was in a semi-conscious condition it was impossible to elicit a satisfactory history. Three were operated on 24 hours after the injury. In two of the cases a marked increased leucocytosis persisted after the operation over a period of from two to four weeks. Three patients had satisfactory convalescence. One died eight days after operation. The fatal case showed a continuous fall in hemoglobin and a decreasing leucocyte count. In the first two cases operation was followed by direct transfusion with apparently good results. From his experiments on animals and his observations he was led to the belief that in certain cases of splenectomy following hemorrhage, death occurred as the result of a severe secondary anemia out of proportion to the amount of blood lost and probably incident to the abscess of the spleen.

Dr. EDWARD H. OCHSNER of Chicago said the paper brought up a number of very interesting points, one of which he would like to mention. One patient, who was doing just as well as the others, developed a severe anemia from which he died. In the experimental work related a number of dogs did not seem to be affected very much by the loss of blood, but a number in the same group showed exactly the same symptoms as the one patient who died. The question which arose in his mind was: Is not this difference in the reaction to the operation by patients or by dogs possibly explained by the fact that some of these patients and some of these dogs had supernumerary spleens and some did not? He believed many patients had an immunity, and a patient who had this immunity and a supernumerary spleen would stand splenectomy. He believed a little spleen tissue was absolutely essential to life.

Dr. F. W. DUBOSE of Selma, Alabama, asked Dr. Willis if there was any enlargement of the lymph glands in his series of cases. The speaker saw a man with a ruptured spleen who, after the removal of the spleen, developed a general lymphadenitis, otherwise his blood and general condition were apparently improved by the operation. The blood was carefully examined every two weeks for a period of three or four months, and within a year the lymphadenitis subsided.

Dr. WILLIS, in closing, said there was no lymphoid enlargement in his cases. All of them did not react alike, and what Dr. Ochsner had said was along the right line. In looking up the literature on traumatic rupture of the spleen he had found 250 cases of normal spleen, and the mortality from rupture varied from 80 to 90 per cent.

The Management of Subparietal Injuries of the Kidney.—Dr. J. M. MASON of Birmingham, Alabama, reported three cases of subparietal injuries to the kidney. (1) Rupture of the right kidney from a fall from a train; death in 20 hours from hemorrhage and shock while preparations were under way for exploration. This was a patient of Dr. B. L. Lester whom he saw in consultation. (2) Contusion or slight laceration of the right kidney due to a fall from an electric light pole. This case was complicated by fractured ribs, fracture of the neck of the left femur, and fracture of the right iliac crest. These complications prevented exploration

of the kidney injury, and the hematuria disappeared at the end of four days, with clearing up of the kidney symptoms, and recovery without operation. (3) Rupture of the left kidney from being knocked down by an automobile. This patient, a girl of 14, was seen on the sixth day following injury. She had hematuria, fever, pain, tenderness and tumor over the left kidney. The kidney was found deeply ruptured in two directions. Nephrectomy; recovery. In all these cases the sources of the hemorrhage and the presence of a second functioning kidney were determined by cystoscopy. He quoted Watson and Neilson, who gave to expectant treatment the highest mortality in uncomplicated cases—27 per cent. as compared with 8.5 per cent. for packing and drainage, and 22.5 per cent. for nephrectomy. He would urge prompt exploration in all cases where the presence of shock or complicating injuries did not demand delay. The advantages of early exploration were summarized as follows: (1) The danger of exploration in properly managed cases was slight, and was not to be compared with the risks of delay. (2) The nature and extent of the injury might be definitely and promptly determined. (3) Appropriate measures might be employed without delay, for the control of hemorrhage, to guard against infection, and to provide for drainage. (4) In certain favorable cases suture of the ruptured kidney might be successfully carried out, while in other instances the kidney might be saved by packing and drainage. (5) A hopelessly damaged kidney might be promptly removed, thereby shortening convalescence and restoring the patient to health in the shortest possible time.

Recurrence of Stone in the Kidney.—Dr. CHARLES R. ROBINS of Richmond, Virginia, stated that the publication in 1915 by Cabot and Crabtree of a study of end results in operations for kidney and ureteral stone, performed at the Massachusetts General Hospital for a period of eight years previous to January 1, 1914, was somewhat startling. In this it was shown that 49 per cent. of the cases suffering from kidney stones and 29 per cent. of those suffering from ureteral stone recurred. In 1917 Braasch and W. J. Mayo published a review of 450 patients operated on at the Mayo Clinic for nephrolithiasis, and on a careful analysis of these cases the recurrences were found to be slightly less than 10 per cent. The question of recurrence of stone in the kidney was brought somewhat forcibly to his own attention by having four cases under treatment at the same time. These happened to be the only patients in his practice that had come back, but there were doubtless others from whom he had not heard. In view of the two very large series referred to above, his individual statistics would hardly add much to the subject. However, as each of his cases showed a different type of recurrences, following a different operation, the histories themselves should be of interest. In dealing with stone in the kidney, he had followed Brewer in dividing his cases into two groups, one in which the stone was apparently the primary condition, and the second where the infection of the kidney was apparently the primary and predominating element. In the first case the removal of the stone was the indication, in the second the cure of the infection, which would usually mean the removal of the kidney, as the infection was ordinarily too advanced and the alteration and destruction of the kidney too permanent to hold out much hope of improvement from any form of conservative treatment. Whether this simple classification met the conditions, further investigation must prove. There could be no question about the soundness of the three principles of treatment laid down by Schede when he stated that the object of treatment was, in the first place, to remove a formed calculus; in the second place, to limit the injury thereby produced as far as possible; and third, to protect the patient against a return of the trouble. The first two had been amply met by the refinements of modern technique, but the third had apparently received very little attention. Previous to the publication of Cabot's and Crabtree's paper, there seems to have been no systematic effort to determine whether the trouble returned or not.

The Treatment of Certain Forms of Subacute Pancreatitis.—Dr. STEPHEN H. WATTS of Charlottesville, Va., believed that all surgeons were agreed that those cases of subacute pancreatitis in which there was

abscess formation should be operated upon and drained, the abscess often being indicated by a palpable mass in the pancreatic region, sometimes filling the lesser peritoneal cavity and even bulging the abdominal wall; but he believed little attention had been directed to those cases of subacute pancreatitis in which the symptoms at the time of operation were not very acute, a diagnosis of gallstones was made and at operation the pancreas was found to be thickened and indurated but still fairly well defined. In these cases there was little or no free fluid in the abdominal cavity, and this not bloodstained, attention being attracted to the pancreas only by the finding of disseminated fat necroses in the omental fat or in the peripancreatic fatty tissues. In previous papers he had emphasized the importance of early incision and drainage of the pancreas itself in cases of acute pancreatitis and had reported four such cases, in three of which recovery followed drainage of the pancreas; in the remaining case, which was a fulminant one, the pancreas was not drained and the patient died; however, he believed there would have been a fatal result in this case under any conditions. In the light of certain cases which he would report, he believed that the same thing should be done on those cases of subacute pancreatitis which seemed to verge almost on the chronic, in fact, he was inclined to believe that some of these represented an acute exacerbation of a chronic pancreatitis. He had operated upon three cases which seemed to belong in this category. In all of these cases a diagnosis of gallstones was made, gallstones were found in the gallbladder, and a cholecystostomy was done but the pancreas and peripancreatic tissues were not drained. In all of the cases fat necroses were found in the omental fat or in the fat about the pancreas and the pancreas itself was somewhat, in fact, in one case markedly thickened and indurated, but the outlines of the pancreas were fairly well defined. The condition, except for the fat necroses, suggested a chronic pancreatitis, therefore the organ was not drained. One of these cases recovered and was in good condition when seen a year after the operation. The other two died, the one nine and the other sixteen days after operation. Autopsies revealed extensive necroses of the head of the pancreas in both cases and in one there was extensive hemorrhage in the tissues about the pancreas. He believed that if pancreatic drainage had been instituted in these cases the result might have been different.

Dr. F. W. DUBOSE of Selma, Alabama, related a case in which a mistake was made in diagnosis. A negress was sent to the infirmary with a diagnosis of enormous fibroid tumor. An assistant made the examination and went through the usual routine tests—blood test, urine test, and so on. He reported that the pulse was quick, otherwise conditions were normal. The author did not make a preliminary examination, nor was an examination made of the feces. On opening the abdomen the speaker saw this enormous tumor with the stomach and duodenum spread out over it and densely and closely adherent to it. As soon as he lifted the omentum and colon and dissected the colon loose from this, he recognized an enormous retroperitoneal tumor, of a character which he had never seen before. He proceeded with the dissection, loosened the stomach and duodenum, and recognized a pancreatic tumor. It involved practically all of the pancreas except the distal three and a half to four inches. This was amputated, the tumor removed, and the distal end of the pancreas stuck into the duodenum, using a double row of sutures. He resorted to hypodermoclysis and as soon as the operation was finished he made use of intravenous transfusion. The tumor, after its removal, was examined and found afterwards to be a sarcoma of the pancreas, globular in form, and measuring about 15 inches in diameter. The woman lived seven or eight hours after the operation.

Dr. ALEXIUS MCGLANNAN of Baltimore stated that if we would do as Dr. Watts had recommended and in addition to draining the gallbladder establish drainage of the pancreas, we were not so likely to have infection that would end in disaster. We would provide an exit for the toxic material which formed and would give the patient an opportunity to get well rather than to absorb the material and die from a fulminating acute pancreatitis.

Dr. LEWIS C. MORRIS of Birmingham, Alabama, stated that about fifteen years ago he operated in a case in which there was marked enlargement of the head of the pancreas associated with stones in the gallbladder. The induration and enlargement were so great that he felt it was definitely a case of malignancy of the pancreas. He removed the stones and made an effort to get a specimen from the head of the pancreas for pathological examination, and in so doing a rent was made in the portal vein, which was clamped and tied off, but no further effort was made to secure a specimen for examination. The woman made a good hospital recovery and went home with the prognosis that death would probably ensue within a year or more. Two years ago he was in the same section of country she came from and had the pleasure of taking lunch at her home. Her case was one of chronic pancreatitis and not of malignancy, secondary to an inflammatory condition of the liver, gallbladder and liver duct.

Dr. GEORGE A. HENDON of Louisville, Kentucky, asked Dr. Watts whether or not in the cases he had operated on there existed in association with pancreatitis a cholecystitis or if gallstones were present.

Dr. JOSEPH RANSOHOFF of Cincinnati, Ohio, did not think it was good surgery to remove a piece of the pancreas for pathological examination unless one knew that the tumor was limited. The smallest kind of wound of the pancreas was apt to bring about by reason of autodigestion an enormous amount of damage. He asked the essayist how often he had made a diagnosis of acute pancreatitis before operation. Personally he knew of no way of doing it. If an acute case had gone on to the degree of suppuration or abscess formation, if the case was not one of hyperpancreatitis, it was possible to make a diagnosis.

Dr. JOHN E. CANNADY of Charleston, West Virginia, asked Dr. Watts to describe a good surgical method of dealing with typical chronic pancreatitis.

Dr. WATTS, replying to Dr. Hendon, stated that in all three cases of subacute pancreatitis gallstones were found. He made a diagnosis of gallstones, and not only found what he went after, but something else. He agreed with Dr. Ransohoff as to the difficulties attending the diagnosis. Replying to Dr. Cannady, he could not speak authoritatively. He thought Dr. LeGrand Guerry could say more about that. LeGrand Guerry thought cholecystectomy should be done, but the speaker had usually done by cholecystostomy.

The Use of Bull's Serum in the Treatment of Wounds Infected with the Bacillus Aerogenes Capsulatus Welchii. Dr. ALEXIUS MCGLANNAN of Baltimore said that Carroll G. Bull had proved that the destructive action of the Welch bacillus was due to a powerful exotoxin. This toxin, injected into muscle and other soft tissue, produced inflammation and necrosis, that is, gangrene, in the absence of the bacilli; and when injected into the circulation it produced an intense hemolysis. The clinical evidences of infection with the Welch bacillus, local gangrene and a hemolytic sapremia, therefore, might be produced experimentally by the filtered toxin. By properly conducted injections of the toxin into suitable animals, Bull had produced a blood serum which neutralized the action of the toxin both in vitro or in vivo. The antitoxin not only neutralized the toxin, but when injected into an animal prevented the development of the spores, and robbed the bacilli of their power to destroy tissue. The antitoxin, therefore, should be given whenever Welch bacilli could be recognized in smears or cultures from a wound, so as to prevent the development of gangrene. When the gas gangrene was already present the injection should be given and repeated every two hours until the fall in temperature and the increase in the number of red blood cells showed that the sapremia had been neutralized. Removal of the gangrenous area by excision or amputation should be done as soon as the patient's general condition warranted any operation. Three cases of infection by the Welch bacillus, with gas and gangrene present, were reported. Two patients recovered and one died. In all the cases the action of the antitoxin was prompt and decisive. In the successful cases the operations were excision of the gangrenous area from a shotgun wound, and amputation of an arm for compound fracture. In the fatal case, a thigh amputation was done following compound fracture, the result of an automobile accident.

The Development and Perfection of the Interposition Operation for Prolapse of the Uterus and Bladder.—Dr. I. S. STONE of Washington, D. C., stated that this operation was a result of the split-flap method of Arx and Sanger, who made a longitudinal incision through the anterior vaginal wall, and separated the bladder from it and the anterior wall of the uterus in the treatment of cystocele. Then came the various methods of Freund, Wertheim, and Mackenrodt, the latter calling his method vaginofixation, which was successfully used to overcome retroversion of the uterus. The methods of Freund and Wertheim, which were shown, involved turning the uterus out into the vagina and fixing the organ permanently in that position. This objectionable procedure was promptly followed by the method of bladder elevation upon the uterus and fixation of the uterus to the entire length of the upper and outer surface of the anterior vaginal wall, immediately upon the former site of the bladder. This operation was exploited by several continental surgeons, each of whom claimed priority, but it was absolutely certain that Duhrssen and Schauta in Germany and Austria respectively and Watkins in America were influenced by those operators who introduced vaginal fixation of the uterus, although they had or should have had the credit of developing, perfecting, and firmly establishing an operation which had proved the most reliable of all vaginal methods of treating prolapse of the uterus and bladder.

Long Resections of the Intestine.—Dr. J. E. CANNADAY of Charleston, West Virginia, said that all of the large intestine or half of the small bowel might be successfully resected. The habitual dietary of a race or a people might modify the length of the intestine to a considerable extent. Certain conditions, such as gangrene, gunshot wounds and tuberculosis, with multiple strictures, might bring about the necessity for such resections. There was a diarrheal tendency after such operations. The wastage of fats and albumins was large and must be met by generous additions to the diet. In the case reported by him there were multiple strictures of the small bowel, due to ileocecal tuberculosis. Ten feet of the small bowel, besides the cecum, and eight inches of the ascending colon were resected. Notwithstanding the fact that the patient had remaining an abnormally short small bowel, five feet, as shown by the post mortem, he made an operative recovery, and died some few weeks later of a fulminant type of pulmonary tuberculosis.

Intraabdominal and Slit Herniæ with Obstruction.—Major FRED W. BAILEY of St. Louis reported a case of hernia through the foramen of Winslow and six cases of slit herniæ or protrusions of the small bowel through apertures in the mesentery of the ileum and jejunum, gastrocolic omentum, omentum, and adventitious membranes. Acute obstruction with perforation of the gangrenous loop was present in the hernia into the lesser cavity, and death resulted. The issue was also fatal in an ileomesenteric hernia with volvulus and perforation. The remaining five recovered. There were four acute and two chronic obstructions in the group. Three of the cases were postoperative cases and three followed inflammatory processes in the peritoneal cavity. Believing that the present-day knowledge of the development, progress, and diagnosis of internal hernia had been clearly covered in the writings of Treitz, Moynihan, Jeanbrau, and Riche, and others, he refrained from unnecessary repetition. The majority of reports of cases of internal postperitoneal herniæ were discovered during operation or post mortem; in virtually all of them, acute obstruction was the predominant symptom; there were certain signs of impending obstruction which made mandatory immediate exploration; in the hands of a competent surgeon the exploratory incision was practically harmless, was a purely diagnostic step, and would, if applied with judgment, greatly lessen the mortality in acute obstruction. He made a plea for a more liberal campaign of public education in the danger signs, especially of acute abdominal disturbances, that early diagnosis and timely surgery might be given opportunity to conserve life.

Some Unusual Surgical Experiences.—Dr. ALBERT VANDER VEER of Albany, New York, said that his experience had brought him in contact with a class of cases, such as foreign substances in the esophagus, tra-

chea, the bronchi, also the rectum, requiring immediate treatment, a few of which he would like to report briefly. A boy, aged 7, while handling his father's lead pencil, loosened the head, and during the act of laughing this portion was inhaled. He coughed a little at first, but this soon ceased, and he was restless during the night. He was brought to the office the next morning, a distance of some fifty miles, breathing with considerable difficulty. On examination no respiratory murmur could be heard over the right lung, although there was no marked dullness on percussion. It was believed the foreign substance had lodged in the right bronchus, possibly just below the bifurcation. An anesthetic was carefully given, a rather rapid tracheotomy done, and curved forceps passed with much trouble down into the bronchus, where the substance could be felt. The first attempt at securing it did not succeed, but the second caught the edge and the tip was removed without any difficulty. Rather violent coughing followed. Upon prompt withdrawal of anesthetic, and after some considerable escape of mucus into the incision, the patient became conscious, was easily calmed, and very earnestly appreciated being told the pencil tip had been removed. He made a rapid recovery, and the trachea healed promptly. This case presented itself previous to the use of the x-ray. The speaker had seen fatal results from the toy mouth balloon, with immediate suffocation, yet with some remarkable recoveries from taking into the bronchus foreign substances, such as a kernel of corn, a bean, peanut shell, or portions of the peanut itself. He had seen some of these substances, particularly a locust pod, expelled as soon as an incision was made in the trachea, when a violent fit of coughing took place. He had also observed the abscesses that would sometimes result from foreign bodies, one, two, three, or four months after inhalation, in consequence of a large enough bronchus connecting with the cavity of the lung. With a sudden expectoration of pus the material would be discovered, although he had never operated upon an abscess of this sort from the exterior part of the chest. Metal substances, like a tack, or possibly a small nail in some instances, when inhaled, as he had observed, would become encysted, but any substance that would macerate was apt to be expelled. The most unfortunate, and quite impossible material to reach was a cork or some such substance. It could not be grasped by any ordinary instrument, and he did not think the bronchoscope had demonstrated reports of a sufficient number of successful cases to warrant much comfort, yet he believed it was in these cases such instruments were to prove of great value. A foreign substance would persistently remain permanently between the cricoid cartilage and the bifurcation, moving up and down, thus giving the child a chance to breathe, although lodged at that point. One such case would serve as an illustration. A girl aged 7 had inhaled a bean, and which was readily recognized as located in the respiratory tract. At times she would have severe attacks of coughing, but substance not expelled. She was brought to the hospital, no effort was made to remove it from above, but an immediate tracheotomy done, the bean found and removed, the patient making a good recovery. Foreign material taken into the esophagus, or the respiratory tract, and becoming lodged and encysted, might sometimes lead us astray regarding symptoms, as we gathered them from the patient. The following case was quite remarkable in many respects. Miss F. N., aged 20, in 1911, while dressing one evening, insisted she had swallowed a black-headed pin about 2 inches in length. She complained of distress in swallowing. The symptoms presented with such urgency that the speaker was induced to do an esophagotomy at the end of 24 hours. This was performed without any difficulty, but he was unable to find the pin at a point where it could be removed, although he could feel it through some thin tissue. He was obliged to admit it was outside of the esophagus, and not safe to attempt any further operative intervention. The patient made a good recovery, having a cough that was prolonged for quite a while, but which eventually disappeared. In the spring of 1916, during a severe paroxysm of coughing, Miss N. expectorated and noticed something in the material which she

thought was a bristle, but upon a more thorough examination was found to be the lost pin. The head had disappeared, and in handling it, thinking it a bristle, she broke off the little point. Here was a mistake in diagnosis. It was quite likely that she had inhaled this into the bronchial tube, instead of swallowing it. In examining her neck there was no evidence of any scar tissue to be observed; she has always had the thorough use of the neck muscles, and no trouble in swallowing. Undoubtedly the x-ray of today would have been of great service, and the bronchoscope most certainly so. Foreign bodies in the rectum had always been a source of considerable thought. Just how to remove them at one time gave him some little annoyance. At first they could easily be felt but not so readily grasped, and he early demonstrated in his own practice that it was safe to dilate the sphincter sufficiently so that a small-sized hand could be inserted, the substance being grasped in that way. It was well known that these foreign bodies had a very energetic way of getting up above the sigmoid flexure into the descending colon. He had come in contact with an ink stand, and such odd articles, but in the case he had in mind the foreign body was pushed into the rectum and caught in this manner. This specimen of candle, such as was used in the passenger cars of years ago, was most remarkable. The engineer of the train suffered from eczema about the anus and pruritus ani, and was in the habit of securing some relief by rubbing the parts with the end of a candle. While doing this on one occasion he suddenly became faint and sat down on the candle, which immediately disappeared in the rectum. It was difficult to reach this foreign substance and remove it, but it was finally accomplished with some considerable trouble by dilating the sphincter, when the candle dropped into view.

Sacral Teratoma; Glioma of the Upper Abdominal Region.—Dr. JAMES E. THOMPSON of Galveston said that the sacral teratoma was removed successfully from a child six months old. The tumor was as large as a cocoanut, and it was removed without any injury to the rectum. The tumor contained cartilage, unstriated muscle, gliomatous tissue, ependymal tissue and cysts lined by epithelium, and glandular elements, in which respect it resembled nearly all the teratomata that had been reported carefully. Its origin was attributed to irregular growth of the posterior growing point of the embryo. The second tumor occupied the upper abdominal region of an adult colored man. It was as large as a Rugby football. It was removed without particular difficulty, but its removal necessitated the removal of the spleen, the tail of the pancreas, and a portion of the greater curvature of the stomach. The patient made a very satisfactory convalescence. Microscopically the growth resembled a spindle-celled sarcoma. Careful examination revealed cellular elements, such as were seen in gliomatous tumors. Its probable origin was the splenic sympathetic plexus. Numerous lantern slides were shown illustrating the histological features of both of these tumors.

Traumatic Brain Surgery.—Dr. JOHN W. LONG of Greensboro, North Carolina, stated that traumatic brain surgery as seen in war was essentially like that of civil life, the principles governing both being in a large part the same. He substantiated his position by quoting from "War Surgery of the Nervous System," a recent volume issued by the War Department under the editorship of Major Seelig, as follows: "The laws of ballistics, trench life, the terrain of the battlefield, the problems of transport, and numerous other incidentals serve to modify established principles of surgery, but not more than that." His message was especially directed to that large number of southern surgeons who were being called from civil to military service. He would have them go to their new field of activity with that self-same confidence characteristic of the American hero, whether professional or in the ranks. They should know that although they go among strange peoples, speaking foreign tongues, their work as applied to brain surgery involved the same principles which they had been accustomed to follow in treating cracked skulls in railroad camps and pistol shot wounds of the head due to the time-honored custom of toting a gun in one hip-pocket and moonshine

liquor in the other. As to the various types of brain surgery, the brain might be seriously injured without wound of the scalp or external plate. Tangential, or gutter wounds, were usually accompanied by fracture of the internal plate, spicules of bone penetrating the bone substance and lacerating brain tissue. The mortality in this type of injury was high. An x-ray picture of a patient who had a penetrating wound of the brain two inches deep, made by a road pick, was shown. The patient was operated upon and made a good recovery. The essayist showed numerous x-ray pictures with abstracts of histories of gunshot wound of the brain, in some instances the bullet remaining in the brain. One case was that of a lad in whom the bullet lodged almost directly in the middle of the brain. A picture taken three years later showed that the bullet was still *in situ*. Many of the cases reported developed paralyses primarily which in every instance were relieved by the operation. Cerebral hernia was one of the most frequent complications following brain trauma. Of 650 patients with brain injury invalided back to England, 120 developed cerebral hernia. The largest brain clinic in this country never had a cerebral hernia. He reported a case of cerebral hernia developing from a late abscess of the brain due to trauma, in which the abscess eroded through the skull from inside out. The patient was operated upon and the skull perforation enlarged, the patient eventually making a good recovery.

(To be concluded.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE MEDICAL EXAMINING BOARD.

June 11, 12, 13, and 14, 1917.

(Concluded from page 133.)

PRACTICE.

1. Describe the symptoms of a moderately severe typhoid fever case at about the end of the second week, and give complications which might arise at that time.
2. What is mucous colitis? Differentiate it from appendicitis and outline treatment of a case.
3. What is aphonia? Give various causes and state how you would establish the diagnosis in a given case.
4. Give signs and symptoms of a well marked case of lobar pneumonia on the fourth day; what would be your treatment at that time?
5. What is the technical name of infantile paralysis? Describe the onset, course and termination of a well-developed case.
6. How would you recognize a case of epidemic cerebrospinal meningitis? Give treatment.
7. How would you recognize and treat a case of delirium tremens?
8. Give symptoms of a brain tumor in central region of the brain.
9. Give etiology of uremia.
10. Name the different clinical forms of la grippe, mention sequelæ and outline treatment.

OBSTETRICS.

1. Describe an acceptable method for relief of intracranial bleeding of new born.
2. Discuss relative value of rectal and vaginal examinations during labor.
3. Describe a practical method of minimizing labor pains.
4. How would you handle an interlocking twin case when both lie head downward?
5. Why is rupture of the uterus more common in the multipara than in the primipara?

SURGERY.

1. Name dangers and disadvantages of spinal anesthesia.
2. Give indications for trephining for Jacksonian epilepsy and describe method of brain localization.
3. Name the common anatomical varieties of hernia and advise treatment.

4. Differentiate cancer of the stomach from gastric ulcer.

5. Diagnose congenital dislocation of the hip and give treatment and prognosis.

PATHOLOGY, BACTERIOLOGY, HYGIENE, AND PUBLIC HEALTH.

1. Describe the healing of a nonapproximated infected wound in vascular tissue.

2. Describe the pathology of acute anterior poliomyelitis.

3. Describe the changes occurring in the heart (a) in aortic regurgitation; (b) in mitral stenosis.

4. Give the histological changes in the vermiform appendix as seen in the process of an acute suppurative inflammation of that organ.

5. Describe the histological picture of an epithelioma or epidermoid carcinoma of the lower lip.

6. Describe three unfavorable terminations of the exudate in lobar pneumonia.

7. Describe the technique of the Widal test and state its value in diagnosis.

8. How would you obtain specimen in suspected diphtheria and give method of making laboratory diagnosis?

9. What hygienic precautions would you take in a case of infantile paralysis?

10. Give in detail hygienic measures to be employed in a case of pulmonary tuberculosis.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF EYE, EAR, NOSE, AND THROAT

1. Acne Vulgaris—give definition, symptoms, and treatment.

2. Give diagnosis and treatment of trachoma.

3. Give indications for the mastoid operation.

4. What is the significance of epistaxis?

5. Give point of difference between follicular tonsillitis and diphtheria.

ANSWERS.

PRACTICE.

1. During the second week of typhoid fever the temperature remains at a uniform level; typhoid state and delirium may be present. The pulse becomes rapid, weak, and dicrotic; the heart sounds are feeble; the tongue is coated, fissured, and tremulous; sordes appear on the teeth; the abdomen is distended; the stools are yellowish and offensive (said to be like pea soup); the Widal reaction may be positive; the spleen is enlarged; reddish spots may be found on the abdomen and chest.

Complications which may arise at this time are: Hemorrhage and perforation of the intestine; also albuminuria and bedsores.

2. "*Mucous colitis*, or mucous colic, is a chronic secretory neurosis of the colon, characterized by the regular or periodic passage of masses of mucus and paroxysms of abdominal pain. The chief phenomena are constipation, the passage of excessive quantities of mucus in the form of flakes, shreds, or casts of the bowel, indigestion, and paroxysmal attacks of intestinal colic. Symptoms of hypochondriasis, neurasthenia, or hysteria are also present in greater or less degree in most cases. Emaciation is sometimes marked. *Treatment*: The diet should be abundant and varied. Bulky foods are recommended. Mild laxatives, preferably frequent doses of castor oil, should be given. Tincture of nuxvomica in ascending doses with sodium bicarbonate is sometimes of service. Mild intestinal antiseptics may be beneficial. Colonic douches, with warm alkaline water or solution of silver nitrate (1:6000), or high injections of cottonseed oil (6 ounces), are often helpful."—(Stevens' *Manual of Practice*.)

For diagnosis of appendicitis, see DIAGNOSIS, Question 6.

3. *Aphonia*, or complete loss of the voice, occurs where the vocal cords cannot meet. Among the conditions which will prevent the approximation of the cords and cause aphonia are paralysis or paresis of the adductor muscles, on whatever cause it may depend; fixation of the cords by cicatricial contractions, or by ankylosis of the crico-arytenoid joints; their destruction by ulceration; any painful affection which makes the patient unconsciously rest them; or coating with

false membrane. But by far the most frequent cause of this aphonia is the abrogation or perversion of the will, occurring in the morbid mental condition of hysteria or other nervous disease; perfect power of phonation existing, but the patient, for months or years, declining to exercise the power, or to make the necessary effort. The intimate relations of the voice to the higher functions of the brain would lead us to expect that it would be influenced by the emotions. Thus we have a person hoarse with rage, speechless with terror, etc.; and the origin of these cases of nervous aphonia is frequently some sudden emotion, causing loss of control over the voice. Ziemssen believes that, even where the vocal cords cannot meet, by a great effort the patient may produce a hoarse, monotonous tone by vicarious vibrations of the ventricular bands.—(Quain's *Dictionary of Medicine*.)

4. *Lobar pneumonia at about the fourth day*: The patient lies flat in bed, often on the affected side; the face is flushed, particularly one or both cheeks; the breathing is hurried, accompanied often with a short expiratory grunt; the alæ nasi dilate with each inspiration; herpes is usually present on the lips or nose; the eyes are bright, the expression is anxious, and there is a frequent short cough which makes the patient wince and hold his side. The expectoration is blood-tinged and extremely tenacious. The temperature may be 104° or 105° F. The pulse is full and bounding and the pulse-respiration ratio much disturbed. Examination of the lungs shows the physical signs of consolidation—blowing breathing and fine râles.—(From Osler's *Practice*.) *Physical signs of lobar pneumonia*: "*Inspection*. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation*. In the second stage the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*: In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining areas the resonance is increased (Skoda's resonance). *Auscultation*. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitatio redux) returns. As resolution proceeds the breath sounds are associated with large and small moist and bubbling râles."—(Hughes' *Practice of Medicine*.)

Treatment: There is no routine treatment. The patient should be put to bed in a well-ventilated room; milk diet, and fractional doses of calomel followed by a saline should be administered. Symptoms are treated as they arise.

5. The technical name of infantile paralysis is acute anterior poliomyelitis. The onset is sudden, and is marked by fever, vomiting, convulsions, headache, restlessness, pain in the bones and muscles. Paralysis sets in in the course of a day or two; the lower extremities are chiefly affected. After a few days the paralysis may become less marked, but the muscles affected atrophy and lose their tendon reflexes. Permanent deformity may occur. Reaction of degeneration is observed.

6. *Cerebrospinal meningitis* has an incubation period varying from a few hours to a week or ten days. The onset may be gradual or sudden (generally the latter), and is usually marked by a chill and rise of temperature. Headache, rigid neck, and hyperesthesia are constant; and vomiting, and mental, motor and sensory symptoms are often present. In fatal cases paralysis, coma, and convulsions have been observed. The *diagnostic factors* are: The presence of the headache, retracted and rigid neck, and hyperesthesia; vomiting, fever, and convulsions; lumbar puncture shows increased pressure in the spinal fluid and the presence of

the *Diplococcus intracellularis meningitidis*. The presence of Brudzinski's sign and Kernig's sign are also said to be diagnostic. *Treatment* includes the use of Flexner's serum (injected into the subarachnoid space after about 40 c.c. of the spinal fluid has been withdrawn). The patient is to be kept in a dark room, with his head elevated (but not flexed) and an ice bag applied to head and spine. Nutrient enemata may be required; both bowels and bladder need to be watched. Nervous symptoms may demand an opiate or chloral; uterotripin is said to be of service.

7. *Delirium tremens*. "Very rare as the result of a single indulgence, this condition is frequent in habitual drinkers. It may follow upon injury, shock, or exposure, or may develop in the course of acute disease. It is to be distinguished from *mania a potu*, a transitory state of acute and often homicidal insanity which occasionally replaces ordinary intoxication in those of nervous heredity. The onset of delirium tremens is accompanied by irritability, restlessness, and disturbed sleep. Tremor is marked. The patient talks to himself, or answers imaginary voices. In a day or two visual hallucinations of moving animals (rats, snakes, or insects) appear, from which he tries to escape, often by springing out of bed; noisy delirium is present; perspiration is abundant; the temperature is somewhat elevated, and the pulse rapid and soft; and there is complete insomnia. Sleep returns as a rule about the third day, but in severe cases it may not do so till the fifth. In fatal cases, death may be due to exhaustion or the patient may die comatose or convulsed.

Treatment: "*Delirium tremens* being due to a toxemia, the first object of treatment is rapid elimination of the poison. Alcohol must be stopped at once, the popular idea that it is required to prevent collapse being altogether fallacious. Treatment should begin with a brisk mercurial purge. Many authorities advise sedatives and narcotics, and push them from the outset. But they do not act unless in large and repeated doses, and these may have a dangerous cumulative effect. Sleep usually returns about the third day; if it does not, sedatives may then be carefully used. Chloral is safer than morphine; and hyoscine, gr. 1/150-1/100, is often effectual. The diet must be fluid and bland, and vigilant nursing is essential. The strait-jacket should be used only when absolutely necessary."—(Wheeler and Jack's *Handbook of Medicine*.)

3. *Brain tumors*. "The symptoms common to all cerebral tumors are: Headache, persistent and increasing in intensity; defects of vision, even blindness, due to an optic neuritis, a very constant symptom; defects of hearing, taste, and of speech, the result of paresis of the vocal cords; vertigo, associated with nausea and vomiting and convulsions, epileptiform in character. These convulsions are usually limited to one side of the body and occur at regular intervals. They may be localized (Jacksonian epilepsy) to one or more groups of muscles and are never attended with loss of consciousness. Nystagmus is sometimes present. Palsies such as strabismus, ptosis, dilatation of the pupil, facial palsy, paraplegia, and hemiplegia are not uncommon symptoms. Defects of sensibility such as sensations of numbness and coldness in the limbs and body may also occur. Occasionally, there are disturbances of equilibrium, manifested by a tendency, when standing, to go backward or turn to the right or left. The intellectual faculties may be well preserved until late in the affection, when irritability of temper, depression of spirits, impairment of memory, emotional disturbances, and a gradually advancing dementia may develop. Slowing of the pulse, insomnia, and increased secretion of urine sometimes accompany cerebral tumors. The focal symptoms of the central region of the brain include motor aphasia, monoplegia, partial anesthesia, and Jacksonian epilepsy."—(Hughes' *Practice of Medicine*.)

9. *Etiology of uremia*. It is an auto-intoxication, due to disordered renal function; nitrogenous substances are probably retained in the blood. Acidosis, the toxic action of abnormal products of metabolism, and failure of some internal secretion of the kidney have also been urged as causative factors. Probably no one theory will explain all cases.

10. *Clinical forms of la grippe*. Respiratory type, gastrointestinal type, nervous type, and the typhoid type. *Sequelae* are: Nervous disorders (such as neu-

ralgia, neuritis, epilepsy, insanity, myelitis, cerebral hemorrhage), otitis media, headache, albuminuria, and chronic nephritis. *Treatment* consists of rest in bed; the pain may be relieved by phenacetin or sodium salicylate; the fever may be reduced by quinine or aconite; the diet must be regulated; liquor ammonii acetatis or Dover's powder may be given; tonics may be required, particularly if there are indications of heart failure.

OBSTETRICS.

1. *Intracranial bleeding of the newborn*. "The treatment of cerebral hemorrhage in infants is symptomatic. It consists of the administration of sodium bromide and chloral, of each two grains per rectum every six hours; mother's milk and quiet; icecap. Human or horse serum may be administered in an attempt to arrest the bleeding. Lumbar puncture may be used for diagnosis; as a therapeutic measure it offers little hope. The same is true of puncture of the fontanel, though in appropriate cases this should be tried. If the symptoms point to cortical pressure, that is, if they are localized, trephining should be considered. More is to be hoped from a decompression operation than we have heretofore expected."—(DeLee's *Obstetrics*.)

2. *Vaginal examination* shows the condition of the vagina and vaginal orifice as regards their patency and freedom from obstruction; also their temperature, moisture, and freedom from tenderness; the condition of the os uteri, its degree of dilatation, thickness, consistency, elasticity; to what stage labor has progressed; whether the bag of waters has ruptured; what the presentation is; the condition of the pelvis, whether normal or deformed; the state of the bladder and rectum. The one disadvantage is the liability to infection. *Rectal examination* is less liable to cause infection, but it is less satisfactory, in that it gives much less information than vaginal examination, and it is more distasteful to the patient.

3. *To minimize labor pains*. "When the pains are well established and are good, strong and regular, much relief may be given the patient by the administration of morphine and scopolamin hypodermatically into the arm or buttocks. The initial dose should be morphine sulphate $\frac{1}{4}$ grain, scopolamin 1/150 grain, followed in one hour by a second injection containing 1/200 grain of scopolamin; if the 'dammerschlaff' is not produced, the scopolamin may be repeated in an hour. The woman continues to have labor pains, but when roused has no recollection of her suffering."—(Polak's *Manual of Obstetrics*.)

4. "When both heads present at the brim, one may be pushed up out of the way by combined internal and external manipulation, and forceps then applied to the other to bring it down into the pelvic cavity. When both heads have passed the brim, push back the second one and apply forceps to the first (the lower) one. Should this be impracticable from the heads having descended too far, the lower head, and then the other, may be successively delivered by forceps. If this method fail craniotomy may be required, preferably on the first (lower) head, the second being more likely to survive. The same mode of treatment may be necessary when one head, having passed the brim, is arrested by jamming of the thorax against the second head, either at or above the brim. When pushing back the locked presenting parts appears impossible, it may still be made easy, in some cases, by placing the woman in a knee-chest position, which should always be tried before any serious operation; the parts go back by gravitation."—(King's *Manual of Obstetrics*.)

5. *Why rupture of the uterus is more common in the multipara than in the primipara*. "Naturally the lax and atrophied uterine wall of a woman who has borne many children does not stand the strain of labor as well as it once did. Then, too, in these days of repeated cesarean section, such a uterus not very infrequently contains a weak spot in the shape of a long cicatrix. Again, such a cicatrix may be the result of efforts to remove an adherent placenta."—(Shears' *Obstetrics*.)

SURGERY.

1. *The chief dangers of spinal anesthesia* are: Infection, injury to the spinal cord, loss of respiratory power, paralysis, poisoning from the drugs employed, and death.

The chief disadvantages of spinal anesthesia are:

The anesthesia is not always perfect; the patient is conscious, and therefore knows what is transpiring; its mortality is greater than that of ether; the after-effects are often severe and protracted, and may be very serious.

2. *Indications for trephining for Jacksonian epilepsy.*—These are thus given in Jacobson's *Operations of Surgery*: The operative treatment of Jacksonian epilepsy of non-traumatic origin is admissible under certain conditions, e.g. if an operable cortical affection (cyst, tumor, or abscess) is probably present. Should this not be so the prospects of a successful operation are slight. Operation is indicated in cases of cortical epilepsy following injury, especially if the cicatrix practically corresponds to a motor area. If at a distance from the Rolandic area the point for trephining should be that indicated by the attack. In all cases scars, spicules of bone, etc., should be removed. In many cases it is advisable also to excise the cortical center.

The motor areas are located and arranged on the cerebral cortex immediately in front of the fissure of Rolando. At the upper part of the convolutions in front of this fissure are areas connected with the movements of the lower extremities; then from above downward are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, larynx, and pharynx. Broca's area (*motor for speech*) is situated in the posterior part of the left inferior frontal convolution (in right-handed persons); it is probably a coordinating area which presides over the efferent impulses which leave the areas of the tongue, lips, and larynx, and which, when properly coordinated, result in speech. The visual areas are situated in the occipital lobes; the auditory areas are present in the superior temporo-sphenoidal lobes, and the olfactory and gustatory centers are present in the anterior part of the temporo-sphenoidal lobe. The areas for cutaneous and kinesthetic sensibility are situated posterior to the fissure of Rolando. There are three association areas: the anterior one in the most anterior part of the frontal lobes; the middle one in the gray matter of the island of Reil, and the posterior one in the posterior portion of the parieto-temporal region.

To locate the fissure of Rolando on the scalp: Draw a straight line over the top of the scalp from theinion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the fissure of Rolando.

3. The anatomical varieties of hernia are:

- | | | |
|--------------|---------------|------------------------------|
| 1. Inguinal | Oblique | Acquired |
| | | Congenital |
| | Direct | Infantile or encysted |
| | | External |
| Interstitial | Internal | |
| | Intraparietal | |
| | Interparietal | |
| | | Extraparietal |
| | | [Incomplete, or Bubonocele.] |
| 2. Femoral | | |
| 3. Umbilical | Congenital | |
| | Of infants | |
| | Of adults | |
| 4. Ventral. | 5. Lumbar. | 6. Obturator. |
| | | 7. Diaphragmatic. |
| | | 8. Pudendal, etc. |

Operative treatment is the best, unless there are distinct contraindications.

For inguinal hernia, many operations are practised, but Bassini's is the most useful. "An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then

sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterward for six months."—From *Aids to Surgery*.)

4.—

CANCER.	ULCER OF STOMACH.
Is rare under forty years of age.	Usually in young adults, especially women.
Epigastric pain is more or less continuous, and not much relieved by vomiting.	The pain is rendered worse by food, and vomiting gives much relief. The pain is also more localized and xiphi-vertebral in character.
Anorexia is marked.	Appetite is good, but the patient is afraid to eat.
Vomiting is not frequent, but is copious; and in the vomited matter the Oppler - Boas bacillus may be found. Cancerous fragments are rare. Free HCl is diminished or absent, and lactic acid is often present.	Vomiting is frequent, and the vomited matter contains free HCl often in excess.
Hemorrhage is seldom copious, but may be frequent ("coffee-ground" vomiting); most common in the later stages.	Hemorrhage is not so frequent, but is copious at times. May be the first symptom.
Loss of flesh; the development of cachexia is rapid.	When the gastric symptoms are severe and prolonged, a cachectic appearance may develop, but never to the same extent as in cancer.
Epigastric tumor is usually easily detected.	No epigastric tumor, though there may be some rigidity of the rectus.

—(Wheeler and Jack's *Handbook of Medicine*.)

5. CONGENITAL DISLOCATION OF THE HIP. *Symptoms.*—"The first evidences are limping, and shortening of the leg, and the trochanter is seen to project. By manipulating the leg with the pelvis fixed, the movements are found to be abnormal, and in thin children the head may be felt rolling on the ilium. The trochanter lies above Nélaton's line, and there is lordosis, and scoliosis toward the affected side, both of which disappear on laying the child on its back. If the child stands on the affected leg, the pelvis (and with it the gluteal fold) hangs at a lower level. In double dislocation these signs are all present, and in addition there is a more waddling gait, and generally more prominence of the buttocks. *Diagnosis* from other conditions. In *rachitic deformity* with lordosis and waddling gait, the bone lies on Nélaton's line, and cannot be moved from the acetabulum. In *coxa vara*, with the trochanter above Nélaton's line, and shortening of the legs, there is inability to abduct them, and no unnatural mobility of the head. In *paralytic dislocation* with displacement similar to that of the congenital form, the head is easily replaced, and there is weakness and flabbiness of the muscles, and paralysis of the legs. In *contractures following tubercular hip disease*, there is want of the free mobility seen in dislocation."—(Buchanan's *Surgery*.)

Treatment is not very satisfactory. If the deformity is discovered before the child walks, an attempt should be made to get the head into the acetabulum and keep it there by fixing the leg in plaster in the fully abducted position for twelve months. From two to five years of age *Lorenz's bloodless method* has its advocates. (1) The abductors which prevent reduction are ruptured subcutaneously by manipulation; (2) the head is replaced in the acetabulum by flexion and abduction, and fixed by plaster with the leg in that position; (3) at the

end of six months the leg is gradually brought down into the straight position. After five or six years of age, *Hoffa's operation* may be done; i.e. the joint is freely opened, the acetabulum is enlarged, and the head is shaped up to fit it. The limb is then immobilized in the abducted and everted position. In many cases a high boot on the side of the deformity is perfectly satisfactory."—(*Aids to Surgery*.)

PATHOLOGY, BACTERIOLOGY, HYGIENE, AND PUBLIC HEALTH.

1. *Healing by granulation or second intention* occurs when the edges of the wound have not been brought together, when the edges have been so damaged that sloughing occurs, when sepsis has prevented healing by first intention. Exudation of plasma and leucocytes occurs, followed by fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibro-cicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in from the edge over the surface, and so the scar is complete."—(*Aids to Surgery*.)

2. *Pathology of acute anterior poliomyelitis.* "The primary changes are in the vessels of the anterior horn (anterior spinal artery), which are congested, distended, and surrounded by small-celled infiltration. Thrombosis is common, but not necessarily present. Secondary interstitial changes take place in the gray matter, and its multipolar cells undergo cloudy swelling and ultimate destruction. Degenerative changes can be traced into the anterior roots. Later, the motor nerve trunks show marked change, the fibers being smaller and fewer in number. The neuroglia becomes increased, and the anterior horn as a whole is sclerosed and shrunken. The muscles are pale and flabby; atrophy begins early and is well marked; and microscopically, they show loss of their transverse striations and increase of fibrous tissue, as the result of destruction of their trophic center. In the epidemic form there may be vascular irritation and cellular infiltration in the higher centers, but the ganglion cells of the medulla, pons, and optic thalamus usually escape. Flexner describes extensive hyperplasia of lymphoid tissues, and necrosis of small groups of liver cells."—(Wheeler and Jack's *Handbook of Medicine*.)

3. In *aortic regurgitation*, the left ventricle becomes at first dilated and then hypertrophied; the heart may become enormously enlarged; failure of compensation ensues. The gradual enlargement of the left ventricle leads to mitral insufficiency with dilatation of the left auricle followed by hypertrophy of the right ventricle.

In *mitral stenosis*, the left auricle becomes hypertrophied and dilated; this is followed by dilatation and hypertrophy of the right ventricle.

4. *Catarrhal appendicitis* is characterized by slight swelling and minute erosions of the mucosa. The muscular and serous coats will show slight infiltration and the lumen will contain epithelial and pus cells. In the *necrotic or gangrenous* variety the inflammatory processes are destructive. The mucosa is destroyed and the muscular and serous layers are soon attacked. The inflammation involves neighboring surfaces and a fibrinous peritonitis develops. This may be local, and by giving rise to adhesions between adjacent tissues no further extension takes place. The process may be very rapid and perforation follow before any restricting adhesions form; this is accompanied by a general and frequently fatal peritonitis. In *interstitial* appendicitis there is a tendency toward excessive connective-tissue formation and it generally terminates as a chronic thickening.—(McConnell's *Pathology*.)

5. "Squamous epitheliomata present themselves as nodular, wart-like elevations of the skin or mucous membrane, tending to become ulcerated on the surface. Those of the mucous surfaces are more elevated and softer. Histologically there are seen branching columns of epithelial cells extending downward from the papillae of the skin into the deeper structures. These consist of large translucent squamous cells which show a tendency to arrange themselves in certain places concentrically to form epithelial *perles*. The latter

frequently undergo a horny transformation and sometimes even calcareous change. Metastasis is frequently seen in the neighboring lymphatic glands, but the malignancy is less marked than in glandular carcinomata."—(Stengel.)

6. *Three unfavorable terminations of the exudate in lobar pneumonia:* "(1) The lung may become the seat of purulent infiltration—diffusely infiltrated with polynuclear leucocytes and appearing yellowish, soft, and puriform to the naked eye. (2) In other cases the lung process goes on to abscess formation (one large abscess or several small abscesses that usually fuse to form a large one)—due often to secondary infection with streptococci and other pyogenic microorganisms; or a portion, or an entire lobe becomes gangrenous—due to defective blood supply and to secondary infection with putrefactive bacteria. (3) In other cases resolution is delayed and may be followed by induration of the lung, or tuberculosis."—(Kelly's *Practice of Medicine*.)

7. Widal's test in typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology*.)

Its diagnostic value is believed by some to be great; others place little reliance on it. It may be absent in cases of typhoid fever; it may be present for several months after an attack of typhoid; the reaction may not be obtained till the third week of the disease; it may be present in other diseases or in perfectly healthy persons. The above have all been urged as objections; certainly, only positive results have any value at all.

8. A sterile swab is rubbed over any visible membrane on the tonsils or throat and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appears as short thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C.

The characteristics of the bacillus of diphtheria: The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aerobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

9. *Hygienic precautions in a case of infantile paralysis:* "No definite or effective system of prevention

can be formulated until we are sure of the mode of transmission. Meanwhile health authorities are entirely justified in requiring cases to be reported, isolated, and all known lines of preventive measures applied, such as disinfection, screening, and guarding against insects, allaying unnecessary dust, etc. A fly campaign directed with especial reference to the stable fly is plainly indicated, and the infection must also be fought as one conveyed from man to man directly. . . . The following measures are recommended: The patient should be isolated as completely as possible in a clean, bare room, well screened to keep out insects. Visiting should be interdicted, and only the necessary attendant should be allowed to come in contact with the patient. All discharges should be thoroughly disinfected, and special care should be taken that cups, spoons, remnants of food, etc., which may have become contaminated by the patient are burned, scalded, or otherwise purified. Towels, bed linen, and other fabrics should be boiled or dipped into a germicidal solution strong enough to destroy the typhoid bacillus. The nurse and physician should observe the same precautions regarding their hands and clothing as they would in attending a case of scarlet fever. . . . Since the virus can be killed experimentally by a 1 per cent. solution of peroxide of hydrogen, antiseptic gargles, sprays, and nose washes of this solution are recommended to be used by the patient, the nurse, and physician, and other members of the family. Street and house dust should be kept down by sprinkling or oiling. During epidemics children should be kept away from public gatherings, prohibited from using public drinking cups, and special attention given to the diet to prevent gastro-intestinal disorders, for many a case of infantile paralysis starts with a digestive upset."—(From Rosenau's *Preventive Medicine and Hygiene*.)

10. *Hygienic precautions to be taken in case of tuberculosis:* "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine*.)

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF EYE, EAR, NOSE, AND THROAT.

1. *Acne* is an inflammatory disease occurring in and around the sebaceous glands, characterized by papules, tubercles, or pustules, affecting chiefly the face, and running a more or less chronic course. *Symptoms:* The forehead, cheeks, and chin are the regions usually affected, although the chest, shoulders, and back are not infrequently involved. The lesions are papular, pustular, or nodular, or a combination of these may be present. Comedones or blackheads and oily seborrhea often coexist, the former frequently giving rise to acne lesions. The primary manifestations are pinhead- to pea-sized, bright- or dark-red, discrete papules appearing at the orifices of the sebaceous glands and hair-follicles. These vary in number from two or three to several dozen. After a period of a few days or weeks the lesions either become pustular and discharge or undergo absorption, being followed by reddish stains or, in some cases, by scars. A new crop succeeds the old, the affection thus continuing for months or years.

Treatment: The underlying cause must be removed; generally dyspepsia and constipation need correction. Hygienic measures such as cold baths, exercise, regular habits are indicated. The diet may need regulation. Local remedies, as sulphur, may be applied in

the form of salves or pastes; ointment of zinc sulphide has been recommended; so, too, have mercurials and the use of the x-rays.

2. *TRACHOMA.*—*Symptoms:* Often the presence of the disease is unsuspected until the lids are everted. Usually there is more or less photophobia and discharge with lachrymation; there is slight ptosis, and the edges of the lid are purplish and thick. When the lids are everted, the upper lid is found most affected. The papillæ are exaggerated so that they look like plush pile (papillary form), and the lymph follicles of the eye are enlarged and prominent (granular form), so as to suggest sago grains or frog's spawn. Both features may be present in one case (mixed form). The discharge is intermittent and contagious; it is rarely great in quantity.

Treatment consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical (surgical) means.

Irritating applications: Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (1 or 2 per cent. solution), glycerole of tannin (5 to 25 per cent.), and the alum stick are also employed.

Mechanical (surgical) treatment includes expression, grattage, excision, curetting, electrolysis, x-rays, and galvanocautery."—(From May's *Diseases of the Eye*.)

3. *Indications for the (radical) mastoid operation* are thus given in Jacobson's *Operations of Surgery:* Generally speaking, the operation is called for in chronic suppuration in the middle ear and mastoid. The following are the chief indications for the operation in a patient suffering from chronic suppurative otitis media: (1) When acute mastoid disease becomes chronic, i.e., the wound behind the ear does not heal, and discharge of pus from the ear persists. (2) Recurring attacks of swelling and pain over the mastoid process. (3) The spontaneous occurrence of facial paralysis. (4) Recurrent attacks of vertigo, either spontaneous or from syringing. (5) When cholesteatomata are present in the attic and the mastoid. (6) For tuberculous disease of the mastoid. (7) For necrosis of the temporal bone or for recurring masses of granulations springing from carious areas. (8) When occlusion of the meatus is associated with a chronic purulent discharge. (9) When intracranial complications are present.

4. *Epistaxis* may be due to some disordered condition of the blood (purpura, hemophilia, plethora, anemia, chlorosis), diseases of the blood vessels, atheroma, syphilis, increased blood pressure (from nephritis, or disease of heart, lungs, or liver), ulcerations and tumors of nose, traumatism, certain infectious diseases (typhoid, pneumonia, measles, scarlet fever, diphtheria, influenza); it may be a precursor of cerebral hemorrhage; rarely, it may be a form of vicarious menstruation.

5. In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms, and may be found on the fauces and pharynx as well as on the tonsil; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

BULLETIN OF APPROACHING EXAMINATIONS

Therapeutic Hints.

Treatment of Lobar Pneumonia.—Scott gives the following therapeutic measures for this very prevalent condition: The open-air treatment is the latest and best in the therapeutics of this disease. The patient must be well wrapped up and protected, and then allowed all the fresh air that is available; it is beneficial in every way, modifying most of the symptoms and aiding all forms of medication. If patients are allowed more fresh air at the beginning of the disease, less call for oxygen will be made at the end; fresh air bears about the same relation to canned oxygen that good porterhouse steak does to embalmed beef.

The diet must be of the most nutritious but easily digested food, and given at periods of every three hours, watching that it be assimilated. A distended stomach and abdomen are dangerous. Strong black coffee throughout the disease is valuable. Liquid or semi-solid substances, such as milk, broth, eggs, etc., are especially valuable.

If gastrointestinal conditions are present, a calomel purge is indicated. The administration of arterial sedatives, such as aconite, veratrum viride, may also be used. In pneumonia of children, small, frequently repeated doses of tincture of aconite are useful in the early stage. Continuous creosote inhalations are beneficial. If heart is weak, digitalis, citrated caffeine, nitroglycerin, sparteine, or strychnine may be given.

During the second stage indications are to sustain the heart and to lessen the fever. Strychnine sulphate, gr. 1/32 to 1/20 every three hours by mouth or hypodermically, citrated caffeine, gr. ij to v, every four hours, or tincture of strophanthus, mxx to x, every three hours, prove strong cardiac allies. The employment of digitalis and nitroglycerin depends on the circulatory conditions. If tension is low, digitalis in full doses is indicated; if tension is high, with right heart embarrassed, nitroglycerin combined with aromatic spirits of ammonia, should be administered every hour or two. Alcoholic stimulants, judiciously administered, are helpful in overcoming cardiac weakness. Small doses are indicated at first and the heart's condition is indicated by the pulse. In the aged or feeble, alcohol should be used from the first. Other indications would be a frequent, feeble, irregular, or intermitting pulse; a dicrotic pulse; delirium, muscular tremor, and subsultus; immediately following crisis, and the period of collapse. Hypodermoclysis of hot normal salt solution is also recommended. When collapse threatens, camphorated oil hypodermically is of great service.

For the cough, morphine, codeine, Dover's powder, citrate of potassium, ammonium chloride, and ammonium carbonate are beneficial.

In the third stage the treatment is a continuation of the second, with the addition of the following formula:

R Ammonii chloridi . . . gr. v to x (0.3 to 0.6)
Strychnina sulphat . . . gr. 1/24 (0.003)
Aqua chloroformi . . . f5j (4.0)
Syr. prun. virg. f5iij (12.0)

SOME THERAPEUTIC CONSIDERATIONS OF PERIODIC MENTAL DEPRESSIONS.*

BY L. PIERCE CLARK, M.D.,
NEW YORK.

THE prognosis of cyclothymia or periodic mental depressions and excitements ranging in severity from the so-called neurasthenic types or simple mental retardation to the severest grade of manic-depressive insanity, is well known to be poor. While recovery from individual attacks almost invariably occurs, making the disorder one of the most benign of the psychoses, the completeness of recovery in the interval period and the possibility of ridding the sufferer from interval symptoms as well as a recurrence of his disorder at some future time, is a problem which psychiatry has still to solve. Fairly obvious reasons why this should be so are in evidence, as shown in the inheritance and the makeup of such individuals. Practically our efforts to overcome these defects in the past have been confined to laying down simple rules in mental hygiene for the individual depressant and warning him especially from the life stresses and conflicts frankly shown to have been precipitating factors in the specific attacks from which he may already have suffered.

For instance, in a cursory review of the literature upon prevention of attacks in periodic depressants, the record is especially barren. The subject is closely bound up with the general rules laid down as prophylactic measures for all individuals with hereditary taint of psychotic reactions. Here the prevention concerns broad rules of avoiding harmful factors which may be social, pedagogic, psychic, or somatic, principles fairly well known to all dealing with psychotic individuals. On account of the innate inability of many cyclothymics to really understand themselves, and furthermore because they are frequently impenetrable pessimists, Kraepelin has suggested the use of hypnotic procedures. He holds that under such a plan the patient may be thereby enlightened both as to the mental state and the causes which produced the condition. Then the physician may follow up such an advantage to further enlighten the patient.

In considering the quality of insight which recovered cases possess, Clark at the Kankakee Hospital found about 10 per cent. had no real degree of insight, which of course gives them necessarily a poor chance of non-recurrences. Bianchi firmly be-

lieved recovered cases ought to make a prolonged stay in the asylum as such a procedure tended strongly to prevent recurrent attacks. He thought the line of treatment which recovers the individual cyclothymic if long continued after the attack, possessed the power to fortify the patient against recurrences—a view shared by many other intramural psychiatrists. Many, including Ring,¹ Storch,² Strohmayer,³ Clouston,⁴ Ziehen,⁵ Pilcz,⁶ Ballet,⁷ and Falret⁸ have used and advised different patterns of drugs and physiotherapy to ward off recurrences. Such plans on the whole seem to be directed toward suppressing an incipient attack and are probably too short sighted in clinical and psychological view of the essential disorder to be largely beneficial to the disease as a whole. For the most part all modern authors are content in portraying a system of bed rest, hydrotherapy, forced feeding and avoidance of all kinds of psychic and somatic insults for the attacks themselves and have little to offer in the way of purely psychic treatment as such for preventing recurrences or for making the interval periods of such individuals quite free from vestigial symptoms.

However valuable the therapeutic principles cited from the literature may have proven in the past, it is quite obvious that such lines of guidance are not yet greatly effective as the interval symptoms are almost invariably present and recurrences of depressions and manic attacks are the rule. A few workers in this special field of psychiatry have made an intensive study of the makeup of the periodic depressive to make clearer the individual problem. While Hoch, for instance, has shown that the periodic depressive or manic individual may have an obvious anamnestic record of having been from earliest life a depressive or "open" type of personality, it is not sufficiently obvious just what is at fault when an individual of this type develops the specific mental disorder. Such studies as this, however, as well as those upon the "shut in" type of the precox and the egocentric one of the essential epileptic, are valuable and pave the way naturally to the more exact and precise analysis of the mechanism by which such psychotic reactions evolve. Such studies tend to make more patent the unconscious or real motives which dominate the periodic depressive in his episodic attack.

While it would be too good to be true to indicate the sequence of a special psychosis by the particular type of makeup of an individual, we may have some hope of moderately approximating this goal by using a quantitative and qualitative analysis of the makeup either in the mildest beginnings of such a mental disorder, during the frank attack, or in the free interval. To search most intently the unconscious forces activating the lives of the periodic

*Read before the Section on Neurology and Psychiatry, New York Academy of Medicine, December 11, 1917.

depressant in this manner is, so far as I know, here undertaken by psychoanalytic methods for the first time with the purpose of seeing whether the interval symptoms and recurrence of the frank episodic attacks themselves may not be aborted or lessened or done away with altogether. One cannot doubt but that many analysts have already undertaken this work in a routine manner, but such data have not, so far as I am aware, been given out in a specific clinical report.

In order to make our thesis clearer it is necessary to restate the clinical groundwork upon which we are engaged, together with the hypothesis of the mechanism of periodic depressions as elaborated by Hoch, and finally to see how definitely our investigations bear out his hypothesis and note the outcome of an analytic therapy upon such material.

As is well known, the course of periodic mental depressions of the simple retardation type, as well as those designated as frank manic-depressive types, are marked by recurrences which may be separated by intervals of comparatively good mental health. There are not a few clinicians who maintain that any individual once afflicted by an attack is never quite free from vestigial symptoms or temperamental attitudes characteristic in such individual types of this psychosis (Stransky). However that may be, usually individuals once free from the specific episode of their mental disorder, are to most intents and purposes well, or at least capable of undertaking the ordinary affairs and obligations of their everyday existence. In a small per cent. they pass directly from one phase of depression or excitement to another without any appreciable interval of so-called normal health.

Even though one or two attacks only occur in the life of the individual, the separate attacks are in no wise essentially different from those who have frequent attacks. It rarely happens, however, that all of many attacks in a single individual are of the same type. On the other hand, one patient during life may suffer from all possible forms, from simple neurasthenoid or hypomanic states (mildest states of excitement) to profound depressions or even stupor. The first attack is usually a depressive one. This is especially true of women. Commonly the first distinct depressive attack runs a mild course and in about half of the cases it is followed immediately by a free interval. A first excitement attack is almost immediately followed by a free interval, seldom by a depressive episode. If the first attack is one of excitement, the majority of succeeding attacks will probably be those of excitement. The duration of individual attacks vary from a few days to several years, the usual duration being from six to twelve months. The free intervals vary considerably in length from a few weeks to many years and stand in no very definite relation to the severity of the previous individual attacks themselves. The intervals are apt to be longer at the beginning and shorter as the attacks recur until the intervals may disappear altogether, the attacks then merging more or less imperceptibly one into another. At the beginning the intervals are usually of one or more years' duration.

In women at the climacteric the intervals tend to become shorter and lengthen out in later life. A few cases in which from the beginning the attacks

succeed each other without marked free intervals, the type of the maximum of the crises is usually light, having little more than mild excitement or simple retardation. Sometimes after a long series of such recurring attacks there may appear a long free interval. Although as a rule during the interval the patients appear quite well, often reenter the family, employ themselves profitably or return to their professions, they are apt to show restraint, lack of independence, a tendency to moroseness, an undue susceptibility to fatigue, some sleeplessness or a diminished capacity to do close or painstaking work, or what is more common, a pettish or irritable mood follows. In addition to these latter temperamental peculiarities such individuals may and often do become more markedly egotistical, unstable, and excitable. They also may present in course of time marked emotional deterioration resulting in poorer social adaptations. Finally in some a weakening in logical thought and memory and a more or less failure in the will and judgment exists. Many patients during the interval fail to show a thorough appreciation of the nature of their disease. Nor do they recognize its serious portent or bearings upon their life activities nor upon the relatives and friends responsible for them. After the milder attacks they often admit they were excited and nervous, but most frequently they attribute it to some fault in the family life or environment. Often in the intervals many patients suddenly develop short periods of moderate exhaustion, flightiness, irritability, and unusual activity. On the other hand they may be unnaturally apprehensive, suspicious, despondent, inactive and indifferent to their various life duties. These transient symptoms of their disorder usually disappear abruptly and in another individual might not be counted as essentially morbid. It is very difficult to distinguish between the mildest forms of cyclothymia and certain morbid peculiarities of the personality. The latter are not infrequent in individuals with a more or less regular vacillation of the emotional life. The depressive periods of ill humor, the impetuous exhilarations are often mistaken for simple whims. They are ascribed to all sorts of deleterious influences, exogenous as well as endogenous. Physicians who believe in the so-called uric acid diathesis, endocrinismus, and auto-intoxication often encourage such patients to look upon their disorder as a purely somatic one. From time immemorial such individuals have been designated as hysterics, neurasthenics, or hypochondriacs since it is only in the depressive states that the patients are brought to the physician's notice or are even considered ill. The patients themselves among the more intelligent class often correctly surmise the nature of their malady and dread its periodic approach. In the milder depressive types the simple lack of decision is often so characteristic that it often suffices for the patient as well as the physician to recognize the real nature of the disorder.

As is very well known, these borderline cases are very numerous, and form a large part of the sanatorium population.* We are here mainly concerned with the therapeutic attempt to see wherein we may

*For the more minute and complete differentiation from the numerous neuroses and psychoses frequently confounded with this special mental disorder, the physician may be referred to the well known textbooks of formal and descriptive psychiatry.

possibly modify in future the present well known unfavorable view of the prognosis of the disorder, especially as regards the certainty of recurrent attacks throughout the life of the individual. Probably all clinicians admit that in the small per cent. of those individuals who pass directly from one attack to another, alternating or continuous, the prognosis is invariably poor. Unfortunately even in the great majority of patients who suffer from this disorder, many psychiatrists have taken such a gloomy view of the prognosis that too little effort has been expended in trying to modify this opinion. The task is doubly difficult, first, because the frequency of subsequent attacks and the duration of the free interval is wholly uncertain. We still have no means of judging just what the future course of the individual case will be. It is usually held, however, that it is safe to predict frequent recurrence of attacks with short intervals where the psychosis manifests itself early and without external cause. If, however, the first attack appears late and follows some external cause, such as childbirth, there will probably be but few attacks. If the disorder appears previous to the period of involution one may expect a recurrence during the climacteric. While in formal psychiatry the descriptive phases of the disorder by Kraepelin, Ziehen and others leave nothing wanting in the clinical delineation of the disorder, we have no clear analysis of the essential mental mechanism of the induction of attacks either of the manic or the depressive episodes, although the work of Hoch, Kirby, and Campbell are noteworthy in this respect. One is bound to agree that in time, after numerous attacks of either or both phases of the disorder, there are often important alterations in the emotional lives of such individuals. The statement is made in face of the fact that such authorities as Kraepelin state that mental deterioration occurs in only a few cases where the attacks appear during the period of development and are long, frequent, and severe. It is held that in the free intervals even these patients are considered well oriented and retain a good memory. So much for the purely intellectual faculties; but it is freely conceded that many such cases show deterioration in habit and conduct, such as indifference, irritability, increased susceptibility to alcohol, and deficiencies in judgment. Such may become in time more unstable in daily attitude toward life, freakish, often becoming schemers or incapable of any consistent and productive employment. In this cursory review of the best modern clinical sense regarding the course and prognosis of periodic mental depressions, while the episodic manifestations themselves are considered benign, the ultimate course and prognosis of the disorder as a whole is gloomy in the extreme. Several points of attack for bettering the prognosis are open to us.

It is the general opinion that early hospital or sanatoria treatment makes for a speedier and more enduring recovery from individual attacks. While this undoubtedly holds true for the frank disorder, perhaps the great majority of individuals suffering from periodic depressions (a term we shall employ to characterize the milder types of the manic-depressive disorder) either in the initial attacks or in a series of attacks are capable of being successfully treated in private practice. This being the

case, the physician is most frequently called upon to recognize the true nature of those protean forms and treat such individuals accordingly. Obviously the majority of cases occurring in such practice are of the depressive type as the individual suffering from the alternating stage of extra well being or hypomanic condition does not submit himself for treatment; or either does not consider himself as ill, or if so, the state is not sufficiently unpleasant to drive him to the physician for aid. As before stated, when the periodic depressive consults the physician, most frequently it is to gain relief from the numerous physical symptoms and only incidentally from the mental symptoms. The case, however, does not remain under observation for long before one is usually made aware that the real seriousness of the disorder is in the mental realm and that, too, in the emotional field of the patient's activities. A careful analysis of the early life of such patients usually discloses a definite abnormal individual, family or social adjustments owing largely to inherent or congenital defects of the instinctive life. Especially is this true in the home life of such individuals when called upon to make the social adjustments at puberty, adolescence, or the later adult life.

In order that some of the lines of therapeutic study here given may be fully understood, it is necessary to recapitulate some of the more recent studies made upon periodic depressions.⁹ These deal with that part of Freudian psychology which concerns *unconscious motives*. For some time antedating Freud's work it was known that in so-called post hypnotic suggestion it was possible to experimentally create motives for action, and that the latter could be carried out without the motive itself entering consciousness. It remained for Freud, however, to reveal to us a new world of such unconscious motives of which we had previously been comparatively unaware. He insisted that these motives of earliest life did not disappear from the individual's life but underwent a further development. From the very nature of their further development the original form of their existence ceased to be a reality to the normal adult consciousness. Freud found on analysis one of the great unconscious motives of the strivings of earliest life was a tendency for a strong attachment of a child to the parent, and particularly a great love for the parent of the opposite sex. One recognizes at once the possible role that such a love attachment might play in the development of the adult love-instinct. But adult love contains sensual elements which are not present in the child, and can, therefore, play no part in that tender feeling toward the parent. However, as puberty approaches, these sensual elements appear. It has been shown that the great task of puberty is to dissolve the bonds of the home tie and to transfer a part of the affections shown previously for the parent to new objects in the service of the instinct of propagation. This puberty-process, for some as yet unknown reason, is not possible to every individual, and the assumption is made that in such instances the trend of the sensual impulse then flows in the direction of the tender feeling formerly felt for the parent. But the conscious personality strongly opposes this process, hence this sexually intensified part of the attach-

ment for the parent remains repressed and unconscious. One may say, therefore, that in the course of adult development certain normal steps remain undeveloped, or are arrested. Hence this defect of undeveloped instinctive desires—which later are the very core of the personality—results in a defective adaptation especially in the sexual sphere, and, as has been carefully pointed out, when one states there is a sexual cause in every neurosis it does not necessarily imply a sexual cause in the adult sense, but in the sense that the cause lies in the imperfect development of the instinct. It has been shown that the unconscious has different depths, as it were, and that the infantile motives just mentioned are undoubtedly among the deepest repressed strivings. But in order to understand these infantile motives aright one needs to free himself from the ordinary adult logical way of thinking and meet the situation on the infantile level. Not a few persons, and even physicians, knowing that Freud has spoken of sexual causes and the child's longing for the parent, have simply combined or translated this into terms of adult sexuality. This is probably wrong, because adult sexuality has many qualities added at puberty which have no such formulation in the infantile life. Often the ideas of desire, expressed in the depressive psychosis in particular, are much more vague. They not infrequently express a mere desire of possession of some sort. This is well shown in the so-called benign psychoses wherein the longing is often expressed as a wish to die with the father or the wish for removal of the mother. "For instance, a woman may become neurotic when she becomes engaged. After marriage she refuses to submit to the marriage relations and then develops a psychosis in which the ideas expressed are essentially that her marriage is annulled, her mother is dead, and that she herself is following her father into his grave and is united with him in his coffin. In other words, it may be inferred in such a case that the woman was unable to adapt herself to her married life and therefore regressed to a union with the father. It can readily be seen that this psychotic setting is not sexual in the adult sense, though it is an evidence of imperfect adaptation of the sexual life."

"There still remains another important point, namely, the thoroughly illogical nature of the above example. On logical grounds it is absurd to wish—and we regard the delusions as expressions of unconscious wishes—that the mother should die, when all that is desired is to be united with the father in death. But the psychosis does not think logically, but autistically, as Bleuler has expressed it. The wish for the mother's death or removal exists, because to the child she is the rival in the affections of the father. We must not forget that the ideas expressed in psychoses are often, so far as we know, direct emanations of unconscious desires which cannot be understood by the observer or the patient when standards of logical thinking are applied to them. And, when we try to cast them into logical or adult form, we are doing something which is, strictly speaking, not possible, and the formulation is apt to become onesided and artificial. To recognize this is important. The vagueness of these trends is not due to our imperfect knowledge of them so much as to their very nature, and we are

not improving matters if we attempt to make them clearer than they really are."

"It has been said that the infantile motives, upon which Freud lays so much stress, have been revealed by a method which is questionable, owing to the great latitude given in it to interpretation. But in studying the psychoses we find exactly the same motives as those which Freud has inferred, and here very often no complicated interpretation is needed, since the unconscious desires are expressed directly in the ideas of the patient. This is what should make the central claims of psychoanalysis so convincing to the psychiatrist. Freudian psychology, however, can be understood only when the dynamic importance of the deepest infantile motives is fully grasped, and this is a side on which even much of the psychoanalytic literature does not lay adequate stress, since it emphasizes more the method and the motives which are more closely related to our adult way of thinking. The psychoses, more than anything else, impress us, however, with the importance of the infantile motives."

In this brief outline of unconscious motives we have the principal teachings of Freud, as elaborated and formulated by Hoch⁹ and applied to the mechanisms of the depressive episodes of the benign psychoses. From the foregoing it will be seen that after the formal and descriptive analysis of the individual case history of a periodic depressive is gone over, the therapeutic inquiry should undertake to make patent and clear to the patient the logical sequences of defective emotional adaptation which his individual life discloses. The next step is to bring into consciousness as far as possible a more complete rationalization of the life activities which were possible at the periods of defective adjustments. Lastly, one may undertake a more strictly psychoanalytic approach by dream analysis and association methods. The latter is not essentially different from that used in treating the neuroses but the inquiry is undertaken with the greatest care as one is dealing with individuals abnormally sensitive and often greatly shocked and pained by the ruthless manifestations of the unconscious motives disclosed in the life analysis.

However, we are justified in going to considerable pains and effort to lead the patient to thoroughly understand his individual conflicts if the method of therapeutic inquiry may hold out a fair hope that by such an investigative treatment the patient may make a better life adjustment, thus possibly preventing recurrent attacks of the disorder.

Before giving an abstract of several cases which have been treated on the above hypothesis, it may be said that the well organized sanatoria or even state hospitals might very properly undertake a similar therapeutic procedure either during the course of the milder depressions or at the end of severe attacks before final discharge to the home is made. The defects of the individual case might also be properly imparted to the after-care social worker connected with the state hospital service in order that she may keep watch over the patient and in case called upon might profitably report to the psychiatrist, or induce the patient to revisit the physician at the sign of serious defect in the emotional adjustment outside. We may be sure that a

wise and intelligent development and cooperation of physicians residing in and outside of the mental hospitals will not long neglect the conservation of the mental welfare of the periodic depressives which at present is so often neglected in the free intervals both by the physicians as well as by their friends and relatives. It cannot be too definitely stated that the above analytic treatment of the periodic depressives must always be carefully adjusted to the individual case both to the nature of the advice as well as the analysis itself. Often the not over-intelligent patient must have the whole matter carefully and very simply explained. And above all the defects of their adjustments can only be of service to the patient when the individual himself comprehends wherein the fault really lies and makes its correction his own vital concern. The method cannot, of course, hope to be of great benefit in the very ignorant, the aged, or those possessing a rigid and fixed mental outlook on life. Even in such cases, however, the trained physician can often, from a simple anamnesis and most cursory survey of the individual's difficulties, use his knowledge of the portent of the defect encountered for a wise conscious guidance of the patient to his lasting advantage.

For the practical purpose of this paper an attempt at a fairly complete presentation of the individual cases is neither necessary nor practicable. It is hoped, however, that sufficient data is offered for one to recognize the clinical type of the disorder under treatment, the main mechanism of their evolution in the specific case, and the result of the analytical treatment as a prophylactic measure, both to improve the mental state of the free intervals, if the latter are to be counted only as intervals, as well as to show that this type of therapeutic inquiry may ambitiously help in rendering some individuals free from recurrences.*

CASE I.—The first case studied was that of a married woman who had passed the climacteric and who had two periodic depressive attacks yearly (simple retardation in type) since her twenty-fourth year. The attacks were characterized by insomnia, mental indecision, and a sense of unworthiness. The onset was usually gradual, the height of the attack being reached in about two weeks. At first the patient developed mental sluggishness. Next, the mental indecision was attended by an inability to speak or write or find words to express herself. Her head felt tired and she could not follow a line of consecutive thought or grasp the meaning of ordinary conversation. She finally talked little as she "had nothing to say." Associated with the mental retardation familiar facts could not be remembered. She remained thoroughly oriented throughout the attacks in spite of the slowness of apprehension and thought. Finally psychomotor retardation became marked and she did little or nothing whole days at a time. All her simple everyday duties loomed before her as insurmountable tasks. She would then say life was useless for her and she had better be left to die. A large part of the time was spent in bed in spite of a persistent insomnia. At the depth of the attacks she had compulsive ideas that God did not exist and that there was no religious hope of immortality, which belief she had entertained all her life. She had full insight. The usual explanation of some unpleasant experience or a change from the country to the city she alleged as the common cause for the attacks. The episodes usually lasted from six weeks to three months.

*More detailed studies of Cases II and III may be found in my previous report, "Mechanism of Periodic Mental Depressions as Shown in Two Cases, and the Therapeutic Advantages of Such Studies," *Review of Neurol. and Psych.*, October, 1914.

The recovery was gradual and there would be about three months of comparative well being, although many irritable and vacillating moods occurred in the interval periods.

Intensive analysis showed that the patient had a very close attachment to the home tie. The marriage was a cold and childless one and the marriage relations were especially unpleasant. It was possible to carry out but little actual psychoanalysis of the unconscious but sufficient was disclosed to show the main tenets of the foregoing hypothesis of the depressions were true and the patient quite realized it. Analysis was carried on through the greater part of one complete but fairly mild attack. Although this patient has been under report for the past seven years no subsequent attacks of depressions have occurred aside from a "slight flurry" of the old depression two years ago, which, however, consisted mainly of a few weeks of interval symptoms formerly regarded merely as "indispositions" of the free intervals. The patient has enlarged her social and community interests, her home life is contented and happy and she has a levelness of emotional "keel" never experienced before and for this she is extremely grateful. One might have expected that this patient was a little too old to show such a good readaptation, but she was remarkably plastic and intelligent for one of her position and station in life.

CASE II.—This was the case of a middle-aged widowed woman with one grown son. She had just passed the climacteric. She had had several recurrent attacks of "neurasthenia" dating from the birth of her only son. The first attack at her son's birth was in fact that of a simple retardation attended by a refusal to eat, a sense of unworthiness, that she was to lose her mind and become dependent upon charity. She could not make mental decisions, wept a good deal without apparent cause and contemplated suicide and even made preparations for it which were frustrated. She did not care for her husband and could not bear to have her child near her. This depressive attack disappeared in two or three months, and ever since, a period of twenty-four years, she has had a short depressive episode every five or six months, sometimes as severe as the first attack, but usually a little less so.

Analysis showed an intensive home tie, especially to the father. Her engagement existed ten years before it was finally consummated in marriage. The marriage was cold and was followed by the first depressive episode at the birth of her son. After ordinary mental analysis had been given our patient submitted to a partial and modified psychoanalysis lasting over a period of several weeks; since that time, four years ago, she has been entirely free from depression or even any vestigial symptoms supposed to persist even in interval periods. She is busily and profitably employed, has widened her social and community interests, and has a continuously hopeful outlook for the future.

CASE III.—This is the case of an unmarried man of the middle thirties who had attacks of simple mental retardation for thirteen years. During that time he had seven distinct and separate attacks occurring at irregular periods, the longest period between attacks being less than two years. The attacks in the main were as follows: He gradually grew quiet in manner, was disinclined to meet social obligations, sat about the house and worried in a mildly anxious manner that he was to lose his job in the city's employ or that other fellow workers were to be promoted above him. In a few days the real depression appeared; he lost his appetite, slept little, grew more restless and vague of purpose, could not make simple decisions and all physical acts were performed slowly. Finally his thought "came slowly" and he thought he was to go insane, was insane in fact, and he senselessly reiterated that he wished he might die, the psychic pain was so intense.

Analysis showed that our patient was intensely attached to the mother ideal, that his emotional makeup was very labile and infantile and that attempts at adult adaptations in assuming an independent position or employment or attempt at getting married were always attended by attacks of depression in which alcoholic indulgences and prostitutions played a certain rôle in his efforts to meet the adult demands. Psycho-

analysis has resulted in the patient's avoidance of any future attacks of depression now over four years. The greater advantages obtained, however, have been in the improvement in his social and business conduct and the elimination of alcoholic indulgence. There is a marked history of periodic depression in the family; the mother herself died insane from exhaustion in a manic attack. Undoubtedly the conscious and foreconscious analyses and psychotherapeutic talks based upon these analyses were very helpful here, but similar efforts of this character by others before had not been productive of such good results as attended the same procedure here, plus a prolonged course of psychoanalysis which broadly covered the entire mental life of the patient. It is interesting to note that certain neurotic symptoms seemingly quite independent of the psychotic depressions were also swept away in the treatment of the main disorder for which the patient sought treatment. The whole therapeutic procedure seems to have resulted in a marked character alteration of our patient's underlying bad adaptive instincts.

CASE IV.—This is the case of a married woman who has passed the climacteric and who had her first attack of simple retardation (neurasthenia) at twenty years of age, brought about seemingly by her father's unkindness to her. She had always been very closely attached to her father. The attack lasted for several months and was characterized by headaches, indecision, motor and psychic retardation, insomnia and thoughts of suicide. The marriage was cold and our patient had her first severe attack of depression at the death of her first child at three years of age. She always worried over this child "from the time it was born." The attack lasted for a year. Since that period she has had more or less severe attacks every year until two years ago, when the state of depression was more or less persistent, with fluctuations of intensity in the depressive symptoms from time to time. The analytic treatment was carried on for a year; it disclosed the dominance of the home tie as a child and especially the father attachment, the really loveless and stressful marriage, the inability to take on the added marriage bond of bearing children, and the final collapse of the effort in frequent "blue spells" and at last a more or less enduring depression. The results of the analysis are shown in the adaptation to home and community life, absence of vestigial symptoms of "blue spells," greater productive work, absence of irritability and fatigue, greater independence, and less sensitiveness and inactivity. She takes a continuous interest in her household affairs, which were formerly indifferently neglected for years. Too short a time has elapsed since the treatment was discontinued (about one year) for it to throw any light on the permanency of the free interval, the advantages of the analytic treatment being as yet confined to the absence of vestigial symptoms and freeing the patient for a natural healthy life.

CASE V.—This is one of a woman now in the early twenties who has had classic manic and depressive episodes since her seventeenth year. There have been several such periods, the majority being manic and followed by depressions. The first "neurasthenic" attack followed an innocent love episode. On its being broken off she was slightly depressed, self-accusatory, insomnia, and had frightening dreams in which there was a reappearance of the father who died some five years previous. This episode soon passed in a month or so, to be followed by the first distinct manic attack after a serious love affair. In this, during the manic excitement, the patient thought there was an actual reappearance of the father. There was a typical flight of ideas, extreme motor restlessness, and a keen antagonism against the mother. In two months this state passed into a slight depression which gradually shaded out into the normal state in three months. The second attack began three days after the birth of her first child. She hoped "the child would be like her brother and father" who were dead. She did not care to see her husband, and when her child was brought to her at her earnest solicitation, under a seeming disguise of extra affection for it she really hurt it in handling it. The manic attack lasted two months and was followed by a short period of depression (six weeks).

The third attack was depressive. She would have nothing to do with her husband and child, read love

stories constantly, and remained in bed the greater part of the time. She was insomnia, ate little, and neglected herself. The period lasted about six months and ended in gradual normal state with many vestigial symptoms of irritability, extra fatigue; she was quarrelsome, moody, and assumed little independence of action. She remained fairly well for one year. The fourth attack was depressive. She disliked her husband and child and exalted her father's virtues in a contentious, querulous manner at the expense of her mother, husband and child. This depression lasted about six months. The fifth attack was a manic one, followed by a depression; both together lasted eight months. In this last period her brothers, mother, husband and child were all *unfriendly* and *distasteful* to her. Only the memory of her father was a "comfort" to her. She had imaginary lovers and hallucinated the return of her dead father and brother.

The analysis showed the intensive infantile attachment to the father and the mother antagonism, the latter openly expressed at three years of age. She encountered innumerable love episodes in early life which were all quite fantastic until her final engagement and marriage. The marriage was treated by her as an inconsequential love episode and a manic attack followed the birth of the child, to whose presence she remained unreconciled for two or three years. The analysis was undertaken at the beginning of the sixth depression, following a manic excitement and continued for six months. The results were shown in a complete readjustment to the mother, brothers, husband and child. The husband and mother report that "for the first time in ten years she has been perfectly normal without nervous and physical symptoms." She has assumed her social and household duties with content, and says, "Now I fully understand, and I have assumed all my adult duties and am quite serene and happy."

CASE VI.—The sixth case is that of an unmarried woman of middle life who for the last five years has had a circular type of mild depression and excitement each lasting six months. The condition developed gradually out of the "natural" fluctuation of her mood for ten years before the definite and precise depressions and excitement which now constitutes her mental life. During the latter part of this five-year period of mental disorder while in a hypomanic state a type of paranoid ideas developed and she undertook analytic treatment as soon as the depression followed this period. The period of depression promptly ceased after the first month's treatment. In the ordinary course of previous attacks this change was not due for at least two months later. In the mild hypomanic state that succeeded this analyzed depression the paranoid trend did not reappear, nor was the excitement so intense as formerly. The patient was able to continue at her rather complicated intellectual and literary work and at the time when the hypomanic period might have been expected to have appeared no depression took place. Instead a milder exhilarative mood nearly normal in character quite comparable to that which she used to experience before the last five-year cyclothymic state developed. However, our patient was too set and rigid in mental attitude to submit to a complete psychoanalysis and only an investigation of the foreconscious was fairly undertaken and carried out. Sufficient data, however, was brought forth in this analysis to show that the infantile fixation on the father and her own egoistic makeup held her back from the development of a normal, cooperative, easy, free and generous emotional adolescence. There was always present a rather "idealistic and poetic concept of soul-mate lover" in the dreams which had an inconstant fixation in real life upon various father types of individuals. Her casual friends believe she is quite well now, but those who know her best can see that she is not as stable mentally as she was a score of years ago, although they consider she is very much better than she has ever been at any time since her distinct cyclothymia has been in existence. She is an only child. Her father is decidedly cyclothymic, having had two distinct periods of "nervous breakdown," one lasting a year. One may at least say here that this patient has undergone great mental reconstruction, but she is probably the least satisfactory as a clinical showing of all the cases

of the series. Unfortunately her present state of well-being is sufficiently comfortable, so she is unwilling at present to attempt further analysis.

In conclusion I would say several other cases of periodic depressions are under treatment but have been so for too short a time for report and at this time. However, sufficient clinical data is here presented, I believe, to show that a modified psycho-analytic approach to these psychoses is a safe and sound procedure and one worthy of earnest trial in the future treatment of such disorders, especially in carefully selected cases of the more promising type of individuals.

FOOD.

CLASSIFICATION OF FOODS; PREPARATION OF FOODS; GENERAL CONSIDERATION OF DIETETICS.

By FRANK F. D. RECKORD, M.D.,

HARRISBURG, PA.

FOODS, considered with regard to their life-giving power, fall under five heads:

1. Those foods which build tissue and repair the daily waste (proteins), such as lean meat, fish, white of egg, milk, cheese, peas, beans, and gluten in wheat.

2. The fatty foods which give heat and energy such as cream, yolk of egg, fat meat, olive oil, and oil of nuts.

3. The hydrated foods which give heat and energy such as carbohydrates; cereals, corn, rice, wheat, oats, buckwheat, potatoes, beets, carrots, and bananas.

4. Those foods which strengthen the bone and purify the blood through their mineral salts, as found in fruits and vegetables.

5. Water, as found in beverages, fruits and vegetables, which dissolves the food and helps to carry it to all parts of the body.

All these foods should enter into each meal each day, and upon the extent to which they enter in the right proportion depends the proper feeding of the family. While it is true that each daily meal should contain a certain amount of each class of foods, it is also true that each class should be represented in an amount to suit the age and occupation of the person as well as to suit his physical condition and the climate in which he lives.

A model meal is one which consists of a few things which are in harmony with the needs of the family, the capacity of the pocket-book, and the time and strength of the housekeeper. If these few things are well cooked and attractively served, the meal will be classed as a perfect one if a spirit of cheerfulness goes with it. Food is meant to sus-

tain life and not to destroy it and yet when too much food, too little food, the wrong sort of food, poorly prepared food, or food taken at the wrong time, is taken into the system, the person so doing is taking one long step toward destruction.

Coffee is not a food, but a stimulant. It should not be given to children and should be taken in moderation by adults. The adult who feels that he cannot do his day's work without the aid of three or four cupfuls of coffee, is the person who should give it up altogether and produce the necessary energy by the use of proper food rather than to spur the organs of the body to overwork, which must result in a weakened condition of those organs. The person who lacks strong nerve control should not drink coffee. The person with a questionable heart action should not drink coffee. The same thing pertains to the use of tea.

The importance of fruit in the daily diet is too often underestimated and fruit is too often looked upon as a luxury rather than a necessity. The nutritive value of fruits lies chiefly in the sugar that they contain. The fig, the raisin, the prune, the apple, and the grape are all fruits which are especially rich in nutritive value. Probably of greater importance, however, is their laxative action and this alone is a mighty argument in favor of the free use of fruit in the daily diet. The prune, the fig, the date, the peach, and the apple are especially laxative. It is a common thing to find children eating nothing but coffee and bread for breakfast and sometimes going to school without food. Cornmeal prepared in the form of a hot mush, served with milk, is an excellent and nutritious food for children. Beware of advising a meal composed of cold cereals alone.

There are certain general principles that are applicable to all forms of food; in the first place, if one desires to increase tissue and, therefore, to increase the intake, there should be especial care that the food is prepared and served in as appetizing a form as possible. This fact is often sufficiently understood, but the point is by no means properly followed up in actual practice, and it is frequently woefully neglected in institutions for the sick. There are many easy and inexpensive methods of making foods acceptable to the palates of the sick poor that are used far less than they might be, largely because they are not known or because the slight effort that is involved in carrying them out is avoided. On the other hand, in cases in which the diet should be restricted, one needs in many instances not only to limit the amount of food, but deliberately to see to it that the manner of preparation is, while wholesome, not too tempting; otherwise the total intake will still often remain too high.

It is also necessary to watch over the methods of preparing food for another general purpose; the more elaborate the composition of food-preparations, the more difficult it is, as a general thing, for digestion and metabolism to deal with them. It has been shown by exact investigations that digestion and absorption are less complete, in many instances, when a number of simple foods are taken coincidentally than when but one of these foods is taken alone, even though the latter be used in amounts equivalent to the previous total.

Also while, as I have stated, a mixture of protein

and carbohydrate, at least, is essential to normal metabolism, it has been almost as clearly shown in relation to metabolism, as it has in relation to digestion, that a variety of forms of these foods and of fats may cause more tax than a small number. Hence, when digestion or metabolism is already impaired, we often limit the variety of food-articles as strictly as can properly be done; and restriction of variety in the manner of their preparation is very commonly still more needful. One of the main reasons for this is that many preparations so intermingle the different foods used that each, so to speak, has to wait until the others are cared for by the digestive juices before any can be well digested. Consequently, digestion is delayed on all sides, and proceeds only bit by bit, and the digestive organs are overburdened and irritated by the undue retention of food; and furthermore time is given for fermentation and putrefaction to occur. Butter, eggs, and sugar may, for example, be well digested when not artificially mixed, but pastry may be very badly borne by the same person.

In many preparations, also, the food is rendered relatively indigestible or innutritious by the manner of preparation, when perhaps even a slight change in the method would have made it wholesome. Meat roasted a long time, until thoroughly done, is less digestible than rare meat, and meat slowly boiled is less nutritious than that quickly boiled.

Furthermore, and this is often more important, elaborate methods of preparation involve the use of relatively large amounts of condiments and sauces of various kinds, and these substances, when used very freely, probably do harm throughout the whole course of their progress from their ingestion to their excretion.

While one must grant that a considerable proportion of persons, particularly among the well-to-do, eat too much total food and too much of certain food-articles, there can, I think, be little doubt that many more persons are damaged by the culinary form in which they take their food. Over-eating consists, I believe, more largely in this factor than in any other; that is, persons in comfortable circumstances more frequently do themselves harm by taking unwholesome food freely than by mere excess in amount.

In this connection may be mentioned the temperature at which foods should be eaten. This cannot, of course, be regulated within narrow limits, but it should be controlled to the extent of preventing the habitual use of very hot or very cold foods or drinks. This is commonly the cause of chronic gastric and intestinal disease, and it often causes acute disturbance also. Ices, and other iced drinks, when taken very slowly and in small amount, are so warmed on the way down that they do no harm, but the complacent American habit of taking them in unlimited quantities, in spite of the objections to them, is a fruitful source of evil. Persons need to be taught that ice-water does not allay thirst so well as cool water, and does much more harm. Often, in very acute gastric disturbance, however, food or fluid, when served very hot or very cold, is comfortably retained by the stomach when otherwise it would be rejected or give distress.

Another general fact is of extreme importance to the severely sick, but also to others, and it is true of

all foods. It is evident without demonstration that the more finely divided and the more nearly in solution foods are when taken, the less irritation do they cause, and the more readily are they digested and absorbed; therefore in acute disease, and in cases of difficult digestion fluids or semi-fluids, or at most, finely divided forms of solids are used. Often even a small portion of poorly subdivided food may cause grave disturbance in such cases. On the other hand, it is common experience that in cases of considerable duration fluids and very finely divided food-articles readily become repulsive. For this reason, and because the gastrointestinal tract, as well as other organs, should not be prevented from performing their normal functions when they can be carried out without damage, such foods should not be used for an unnecessarily long time.

Preparation of Meats.—Meats, if finely divided, are usually slightly more digestible when raw than when cooked. There is, however, danger of bacterial and parasitic infection when they are used raw. For this reason, and still more because they are usually more palatable when cooked, they are in this country seldom taken in the raw state.

The methods of cooking have an important influence upon their digestibility as well as upon their palatability. The chief methods are broiling, boiling, frying, and roasting. As ordinarily done, broiling and roasting are the only thoroughly acceptable methods. Frying is never wholesome, because when cooked in this way, meats are usually harder, more of the albumin being firmly coagulated, unless the frying is very well done; and because also the fat used in frying so permeates a large part of the meat as to make it difficult for the gastric and intestinal juices to get at the lean and digest it.

Boiling, when well done, is a good method; when not well done, a poor one. The chief point of importance concerning boiling is that raising the temperature slowly removes salts, extractive substances, and a very considerable part of the nutritious and very digestible soluble albumin. On the other hand, placing the meat in water that is already nearly or quite boiling quickly coagulates the external portion, and this prevents the extraction of much nutritious material, for the coagulated portion acts as a more or less impervious coating. Hence, when the meat itself is to be eaten it will taste better if boiled quickly, because the substances that lend flavor are extractives, and these are largely removed in slow boiling. The meat will also be more nutritious when quickly boiled. If, however, it is being boiled in order to make soup or broth, slow boiling is essential in order that the soup may be well flavored and nutritious.

In all instances when cooking meats it is to be remembered that prolonged cooking at a high temperature firmly coagulates the most digestible and nutritious portions of the meat, and thereby makes them less digestible than when they are cooked for only a short period. Prolonged cooking, particularly prolonged boiling, may dissolve and loosen a good deal of the denser connective tissue and make the meat seem, upon superficial observation, more tender, but as an actual fact it merely makes the meat more easily fragmented, while the individual fibers themselves are harder to digest.

It is a well-known fact that keeping many meats for some time before they are eaten is essential to making them tender and highly flavored. There have been various theories as to the cause of this, but recent investigations have shown that it is the result of a natural partial predigestion of the meats. The ferments present in the tissues, if time is given them, carry out a partial autodigestive or autolytic process which softens the meats, and substances formed in this process heighten the flavor. This is one of the many instances in which accurate investigations have ultimately demonstrated that many, if not most, such general customs are based upon rational physiological principles, although the customs may have been empirically established.

The Preparation of Carbohydrates.—The preparation of carbohydrates is, in many of its most important parts, carried out before these foods are purchased, except in connection with the fresh vegetables. In the preparation of cereals, the indigestible cellulose and woody fiber are usually removed and the cereal is frequently finely ground. The effect of this is to remove most of the irritating elements of the food; consequently the only way in which such preparations are likely to upset the digestion afterward is through the possible occurrence of fermentation or through promoting constipation. With irritable digestive tracts only cereals that are finely ground, largely freed of cellulose, and thoroughly cooked are permissible. With sluggish digestive tracts, on the contrary, especially when there is constipation, the less finely ground cereals, more particularly those that contain all the elements, including the cellulose (whole-meal preparations), are valuable.

In the domestic preparation of carbohydrates the elements of chief importance in sparing the digestive tract are fine division of the food and thorough and prolonged cooking. The cooking, as is well known, causes the starch-granules to swell and ultimately to rupture, and this accomplishes the most important purpose in their preparation, which is to make the starch accessible to the diastatic ferments of the digestive tract. When prolonged, cooking also converts some of the starch into fluid starch, and even partially predigests some of it into dextrins, small portions of it, indeed, becoming digested as far as the maltose stage. Cooking also softens the cellulose and thus helps to break up the food into small particles, or to make it easy for the individual to do so in mastication. For this reason it is of vastly more importance than is usually recognized to have carbohydrate foods, and especially those that contain a good deal of cellulose and woody fiber which is closely intermingled with the other substances, cooked very thoroughly. Such foods, for example, are all the green vegetables, tubers, such as beets, carrots, parsnips, and turnips. Unless young and tender, they are relatively indigestible, at best, and they become a suitable food only after very prolonged cooking. For persons who have troublesome digestions they should also be very finely divided, as by being put through a colander.

The Preparation of Fats.—The most important element in the preparation of fats is to avoid their too intimate mixture with the other foods with

which they are served. A French salad-dressing, for example, in which the oil is nearly free, is with most persons comparatively digestible, while a mayonnaise is, as a rule, very indigestible.

Another point, however, is frequently of much importance: With delicate digestions, the chief factor in making the fats digestible is usually to give them in a finely divided form or in such form that mastication will finely divide them. The first is done with artificial emulsions and the latter can sometimes be done in cooking. For example, in addition to the effect upon the appetite, a piece of greasy, dripping bacon is much less easily digested than a piece that is crisply cooked, probably chiefly because the latter can be very easily broken up into small fragments in mastication.

Preserved Foods.—But few points concerning preserved foods need be mentioned here. In the first place, as is well known, all kinds of preserved foods, but particularly meats, occasionally undergo some degree of decomposition, and this more especially occurs when the containers in which they are purchased have been opened and the food has been exposed to the air for some time before it is eaten. Preserved foods, unless preserved by chemicals, often more readily undergo decomposition when the opportunity for bacterial invasion is given than do fresh foods; it is, therefore, quite true, as is commonly supposed, that they should be eaten reasonably quickly after they are opened, or not at all. It is improbable that there is any truth in the common belief that, if left in the can, some specially toxic substance forms. It is more likely that the whole matter is merely a question of bacterial invasion.

Nearly all the preserved foods bought on the market contain some form of antiseptic or chemical preservative. Whatever view may be taken about the use of these substances in small amounts by normal persons, I think that there can be no rational doubt that most of them are irritants and tissue-poisons when taken in considerable amounts; therefore, when one is especially shielding the digestive, the metabolic, or the excretory organs, even from very slight irritants, I think the patient should be instructed to avoid any foods that are preserved by means of chemicals.

Those foods that are preserved by such domestic measures as the use of sugar-solutions, salt, smoking, etc., are, as a rule, less digestible than the fresh foods; for delicate digestive tracts they are, therefore, less suitable, although in varying degree. Salted and smoked meats are usually somewhat toughened by the process of preserving, and the large amount of salt contained in the former may damage digestion, metabolism, or excretion. On the other hand, preserved vegetables and fruits are at times, through the prolonged boiling to which they are subjected, often made more digestible than they were when fresh, providing large amounts of sugar are not used in preparing them.

Certain General Considerations.—In the first place, in cases that are at all difficult simplicity in the diet is one of the most important things—more important, perhaps, in the general run of cases than any other one point. Its value lies chiefly in two directions: First, the patient will often adhere more closely to his diet if it is made severe at first, but

the prospect of a frequent increase in the variety of foods is given him. More important than this, a disturbed digestion and metabolism can deal much more easily with a small number of food-articles than with a large variety.

The mere fact that food-articles contain a certain amount of protein, carbohydrate, fat, salts, and water is but a small part of the knowledge that we should have of their composition and their effect upon digestion and metabolism. We know already many minor differences, and there are many more to be learned. Even though these differences may have little or no influence when only a small variety of bland foods is given, each difference in detail complicates the task that the digestive organs and the tissues must complete in making use of the food. A weary brain may do a few simple things well, but will do a multiplicity of simple things ill; likewise, a weary digestion or metabolism may deal very readily with a few simple foods, but be undone by a great variety, even though all are individually suitable.

A very large proportion of gourmands, then, suffer not so much because they eat too much food, as because they take a diet that is extremely varied and elaborate, particularly in the manner of its preparation. On the other hand, it must always be remembered that the variety in food-articles must, when possible, be made reasonably large; otherwise, the appetite soon fails, and the patient becomes undernourished. Great simplicity, therefore, cannot ordinarily be wisely continued for any considerable length of time, unless circumstances force this upon one.

In many cases of acute digestive disturbance temporary entire withdrawal of food is the most important point in the whole treatment. This is but too rarely appreciated and acted upon. Persistent vomiting, of course, demands it, but it is important in much less violent disturbance of the stomach and in great irritability of the intestines, especially when foul bowel movements show that excessive putrefaction is going on. The extreme value in some cases of temporary starvation is becoming widely recognized in dealing with young children, but it needs to be even more generally used with them in proper instances; and with adults its great usefulness is much less extensively appreciated. Just as it gives the gastrointestinal tract opportunity to empty itself of irritating material and to rest for a time, so does it permit of the excretion of toxic material in toxemias, and provide some rest for the organs of metabolism and excretion. Consequently, it is frequently useful in some toxic states due to disease of the liver or kidneys, as well as in gastrointestinal disturbance.

It is a long-established fact that irritability of the stomach or intestine usually necessitates small meals, the proper total amount being then secured, as far as is possible, by frequent feedings. Large bulk usually means in such cases that the stomach expels the food quickly by vomiting or by driving it on into the intestine before it has been properly prepared for intestinal digestion.

Diarrhea is often caused or prolonged in both acute and chronic cases by taking unduly large meals. In some instances, however, large meals taken at wide intervals are better borne by a dis-

turbed digestive tract than are small or moderate sized meals that are taken at more frequent intervals, but this is relatively uncommon.

David Edsall says that one factor in producing much of the gastrointestinal disturbance in America is the very large breakfast habitually taken by many persons. Although the interval since the last meal is a long one, there has, as a rule, been almost no work or exercise in this interval, and therefore a large meal is not usually demanded. At any rate, as a practical fact, a large number of persons have better digestion when a rather small breakfast is taken, and Edsall has repeatedly known this to relieve chronic digestive disorders.

On the other hand, it is common, among young women especially, and particularly among those who work for their living or who are much pampered, to take little or no breakfast, and this is a common cause of poor general nutrition, headaches, a chlorotic state of the blood, and other disorders.

Similarly important is the fact that many articles of food that are, for people in general, digestible and nutritious, cannot be taken by some individuals without ill effects, owing to some more or less obscure idiosyncrasy. Milk, for example, which, with the great mass of humanity, is very easily digested and is more nearly a complete nutriment than any other single food-article, is sometimes a poor form of nourishment. This, however, is far less frequently the case than many persons believe. Most commonly, the difficulty in taking milk is dependent upon repugnance for it, erroneous preconception, bacterial infection of the milk, or factors that can readily be overcome by simple methods of preparation. In such cases flavoring the milk with a little salt, tea, coffee, cocoa, or some preparation of alcohol will often overcome this repugnance; it will also frequently make the milk digest better, probably because it does make it more palatable. Adding gruel or an alkali to milk will often modify the curd, and will frequently overcome the digestive disturbance that it causes, with adults as well as with children. The fat is commonly at fault, and in that case skimmed milk will often be well taken. Very frequently, indeed, especially when there is already delicacy of digestion and hence susceptibility to infection, heating the milk will stop any gastric symptoms, intestinal fermentation, or diarrhea that it produces—partly through the chemical and physical changes that heating produces in the milk, but much more because it kills the bacteria in which most market milk abounds. The latter fact is now pretty generally recognized in treating young children, but it needs to be far more widely appreciated in the care of older children and adults than it yet is. In spite of all these measures, however, milk is, in a small number of cases, extremely repulsive, or it persistently causes untoward symptoms without any evident good reason. In such cases it is not a good form of nourishment, and something else must be given in the place of it.

Similar statements are true of eggs. Instances are not uncommon, especially in young children, in which eggs cause more or less severe disturbance, particularly of the stomach, even though taken raw or but slightly cooked, and even though the manner of preparation may have so far disguised the

taste of the eggs that the patient did not know that he had eaten them. This is generally due to the yolk, and caused by the fat in it. Such patients can usually take egg-albumen with great freedom. In some curious cases, however, it is due to the albumen.

Very many persons believe that they have an idiosyncrasy toward fish and other seafoods. These foods not infrequently cause digestive disturbances and signs of general poisoning, but while these are at times due to a peculiarity of the individual, they are much more commonly due to the fact that seafoods are very likely to undergo bacterial changes before they are eaten.

There are, however, other real and important idiosyncrasies, such as the curious toxic symptoms that may result from eating strawberries and some other fruits, and the milder symptoms that seem to be caused in individuals by many other foods. Such peculiarities, if they seem to be real, should not, except for very especial reasons, be fought, but should be yielded to.

The appetite also often has to be pampered for other reasons, by fair means or foul. One sometimes mildly deceives those that are habitually heavy eaters, and insist upon filling their stomachs, by permitting them to eat freely of foods that have a large bulk, but only a small fuel-value. In obesity, for instance, and in some digestive disorders, that permit of this, the sensuous gratification that results from this measure frequently leads the self-indulgent patient to persist in proper treatment when otherwise he would rebel. The same purpose may often be accomplished in another way: one may grant some degree of freedom in the amount of food, but exclude the use of condiments and sauces and of water at meals. The patient then usually reduces his intake unconsciously. When, on the other hand, the appetite is so depressed that too little food is taken, one may often, if this is suitable for the digestion in the individual case, increase the intake by giving food in as concentrated a form as is compatible with attractiveness; but the appetite should especially be stimulated by delicate methods of preparing and serving the food, by using condiments, or by various other devices, such as beginning the meal with a small amount of some light but stimulating and agreeably flavored food-article like bouillon or fruit.

Mere insistence upon the patient's taking a much larger quantity of food than his appetite calls for is a very unsuccessful and ill-judged way of treating malnutrition from any cause, unless it be hysteria, insanity, or the anorexia that may develop in severe emaciation and inanition.

The appetite needs to be carefully considered, also, when one establishes regulations that differ largely from normal customs or the patient's habits. In such circumstances, particularly if the restrictions imposed are pretty narrow, the food-articles ordered readily become repulsive, and the patient, then, if he adheres to his diet, may become ill-nourished, merely because he can take only a small amount of what is permitted him. For this reason one needs, in cases that are at all protracted, to be careful to restrict the diet only so far and so long as is essential, especially if there is danger, already, of malnutrition. Very often, indeed, one's chief

duty is to enlarge the diet, because the patient is suffering from the effect of a restriction that has been imposed upon him, or that his own overfearfulness has led him into. In fact, one of the most common and most serious errors made in dietetics is to advise, or to permit the patient to carry out, too great a restriction in the amount and variety of food, and thereby to produce more or less serious malnutrition that is very often worse than the original disorder.

There is another fact that is dependent partly upon the frailties of the patient and partly upon the carelessness of the physician: Diets are very frequently adhered to but loosely. This is extremely difficult to control, in many instances, in family practice, and hence patients that need rigid regulation of their diet often do much better in institutions than at home. This trouble, however, can be largely overcome if one is absolutely definite and specific in stating the constituents of the diet, the character of the separate meals, and the time at which they are to be eaten; and, as far as possible, in regulating the amount of the different food-articles permitted. All these statements, in all cases in which the diet is of decided importance, should be written out in detail. Furthermore, the patient should be required to keep a record of his meals, and this should be carefully supervised and controlled. When a list stares him in the face, he cannot plead a lapse of memory, and specific statements, together with a sense of being frequently under detailed inspection, serve as a very effectual control in most instances.

The most important things that we actually do in employing dietetics are really comparatively few in number in most cases; first of all, one of the most important things we have to do is to study carefully the dietetic habits of the individual and correct anything that would be essentially wrong for any one. The great variety of errors in diet that we find, and the commonness with which they are present, makes this one of the most important features of dietetics, and it must always be remembered that it is not a question of discovering a person's indulgences only, but frequently of discovering rather bizarre fancies, or peculiar family customs, and a variety of other things which unconsciously to the patient are doing him harm. Then we must determine whether the patient is undernourished, overnourished, or normally nourished, and if he is either of the former we must correct this, if possible, by choosing amounts and kinds of foods, according to their known values. Then, in a large proportion of cases, whatever the disturbance, particularly when it is digestive, we shall find it desirable to limit temporarily both the amounts and the kinds of foods—that is, to put the patient upon a somewhat insufficient diet for a very short time, and upon an extremely simple variety of foods, in order that opportunity for rest may be given as an important part of overcoming the effects of previous errors. This, however, is by no means always to be done, as in many cases the patient needs from the first to get more generous feeding, and in any case underfeeding should continue for only a short time, and the patient's general nutrition must be constantly watched, as there is always danger of damaging it through dietetic

regulations unless this is guarded against. In disturbances of digestion, whether the main condition producing them is disease of the digestive organs or of some other kind, we are influenced relatively little by the name of the disease, except in so far as we know that the disease involves certain dangers, and, therefore, demands a severity of restriction that we otherwise might not use. We are influenced, on the contrary, first by the evidence of irritation, and in accordance with the severity of any signs of irritation, such as nausea, vomiting, pain, gastric hypersecretion, diarrhea, we permit only foods that are more or less simple and bland in their physical and chemical characters. Again, we always have in view the necessity of stimulating peristalsis and the expulsion of fecal matter by choosing foods that leave a residue or that yield substances that excite peristalsis, or, on the other hand, if this function is already excessive, we exclude precisely such foods and use those that have the contrary effect. Finally, and in a large proportion of digestive cases, most important of all, we determine, by a study of the feces, which type of foods is giving disturbance, and just as is done in infants and young children, we restrict the protein, carbohydrates, or fats in accordance with this; or, better, when possible, we choose reasonable quantities of these from those forms that are easily digested and do not readily decompose in the digestive tract. The principles that have been established by the careful studies of pediatricists are nearly as applicable to adult patients as they are to the very young, and they need to be followed much more than they are. Indeed, pediatricists are much more rational in their dietetics than are the mass of those who deal with adults; very naturally, however, because it is so much easier for them to determine, in the much less complex pathological circumstances of very early life, which is chiefly at fault.

In dealing with diseases which lie beyond the digestive tract, we have, in most instances, except in diabetes and obesity, only general conceptions to work upon, such as the existence of intoxication, for example, which demands some flushing with water, limitation of the foods to such as are relatively easily metabolized and excreted, and restriction of the amounts of these as closely as can be done without damaging general nutrition—all this so that the powers of metabolism and excretion may be spared for the control of the toxemia; or we know, for example, in hepatic cirrhosis and such conditions that something is causing chronic irritation, and we make regulations that are in the main the same as those above mentioned, in order to meet these conditions. Much the same thing is true in chronic nephritis. In other conditions, there are certain details that are especially suitable in some of these conditions, rather than in others, but the most valuable of all the regulations that we possess are covered by a scheme such as that I have sketched, and one strikes much nearer his aim if he fixes such a scheme as his basis of action, and slowly adds special details, as study and experience demonstrate to him their importance, than if he starts with the belief that he must arrange first the details to fit each condition.

220 KELKER STREET.

THE PROBLEM OF "NEUROTICS" IN MILITARY SERVICE.*

SOME RECOMMENDATIONS.

BY ALFRED GORDON, M.D.,

PHILADELPHIA.

IN the selection of men for defense of our country and for bringing the war to a successful conclusion not only the quantitative form should be taken into consideration, but also the qualitative value of each soldier. There is a class of men who are very little understood whose manifestations are being regarded as spurious, imaginary, and consequently of too little importance to be considered at all. The average medical man ignores their complaints because of absence of concrete physical signs. In reality there is always present a multiplicity of physical disturbances alongside of psychological factors which are sufficiently powerful to cause actual and genuine disability and unfitness for responsible military work in war time. The other reason why these cases are treated lightly is the fact that the individuals show a strong tendency to recover promptly, but unfortunately those recoveries are only superficial and recurrences are very frequent. In the latter feature lies the essential characteristic of the patient's condition, and so-called recoveries take place only in the episodic morbid manifestations, but not in the underlying fundamental nature of the individual. Without entering into a detailed definition of various forms of functional nervous disorders of a psychological bearing, I will use for present purposes the general term "neurotic" to cover the vast field of individuals whose mental make-up is such that at any time during life, under the influence of the least emotion they are apt to develop mental or physical disabilities of a functional nature so as to render them useless in the community. Recognition of such a type of individuals and of their psychic mechanism is of paramount importance at present, as it is urgently essential to know who is fit and who is not fit to undertake the great task of protecting his country. It is gravely important for us to know beforehand who is capable or incapable to withstand the horrors and hardships of war, as success will depend on the selection of the first group and on the weeding out of the second group. The subject is therefore of immediate vital importance.

Let us briefly outline the essential characteristic features of the "neurotic" individual.

The most conspicuous and the most important is a want of equilibrium in the intellectual faculties, and the mental instability may sometimes be extreme. Such individuals are introspective, emotional, timid, extremely sensitive, impressionable, suspicious, and egotistic. Their psychophysical resistance is constitutionally diminished and there is an interruption of harmonious equilibrium normally existing between various functions of cerebrospinal centers, and consequently the co-operation and adaptation of the latter are incomplete. It does not require a special mental effort to conceive that individuals of this psychic make-up are apt to develop morbid manifestations of any sort

*Read before the Philadelphia County Medical Society, January 9, 1917.

under the influence of some emotional factor. In practical life we observe that depressive emotions, prolonged physical or intellectual efforts, a prolonged waking state, excesses of any sort, or disturbances of nutrition and intoxications are the usual causes of neuroses in neurotic individuals.

Among the various neuroses which a neurotic most frequently develops is a so-called "anxiety state." As an illustration the following example may be presented:

A young attorney of 25, who frequently during his student days suffered from obsessive ideas, with morbid impulses, has now developed a morbid state of a different kind. He expects to be called to the colors. Being constantly in a state of tension, he is extremely restless, irritable, has difficulty of concentration so that he frequently neglects his work, sleeps very poorly, is easily startled when he falls asleep, dreams constantly, and sees in his dreams fighting, with bloodshed. He feels always fatigued, and sleep does not refresh him. He is very apprehensive, reads the war news in as many editions of newspapers as he can procure. He is in a state of disquietude, converses frequently regarding the issue of the war. Any bit of news unfavorable to the Allies accentuates the above symptoms and precipitates a prolonged insomnia, with all its horrors. Formerly he suffered from periodic imperative micturition. Now the disorder became so persistent that he is obliged to urinate every half hour. This phenomenon is associated with a state of tension in the perineum. In arguing once a case in court he was obliged to excuse himself several times and go out to empty his bladder. When the time came for him to address the jury he was thrown into such a state of anxiety that he was unable to go further than to say: "Gentlemen of the Jury." One may infer at first glance that the element of fear is the chief etiological factor in the neurosis of my patient. However, I may say that he was a man of high principles; he was truly patriotic, which he has demonstrated in various ways; he was eager to do "his bit," but his psychic mechanism was such that a manifest instability would occur upon the least provocation. Soon he developed nightmares and of course he would awaken in cold sweats and terror, frequently screaming. They became so frequent that he commenced to fight sleep, because he actually feared sleep, which, of course, deprived him of sufficient rest. For days he would get but a few minutes at the time of actual sleep. The facial expression corresponded to the mental state of my patient. It manifestly revealed an emotional strain; the features were drawn, forehead frequently frowned, and there was an evident effort to maintain control of himself; there was an evident mental pain. The patient, being perfectly conscious of these disturbances, feared intensely that because of them he would not be able to fulfill his duty towards his country. On the other hand, in case of being rejected by the military authorities he feared that he might be considered by his friends as cowardly and unworthy. This fear intensified his "state of anxiety," and he spent days in actual mental agony.

Such is briefly the picture of the neurosis called "state of anxiety." In some cases it may be more, in others less, pronounced. One of its characteristics is improvement and even disappearance of some or all of its manifestations, but on the other hand recurrences are equally characteristic of this affection. The above patient improved greatly after each attack, but the neurosis would soon return. The most interesting and important feature of the subject under discussion is that such individuals appear objectively normal. So it was with our patient. To all his friends and relatives he was a man of good physical health. Indeed, with the exception of the above mentioned urinary symptoms, there was at no time any somatic disturbance. He

knew that duty called him to join the forces and that he would cheerfully assume the duties assigned to him, but the intense fear of being unable to face responsibilities of grave nature made him feel great shame over this and caused the disturbances enumerated above. Does not that feeling of fear or the state of anxiety indicate grave defects in the individual's attempt to adapt himself to new conditions and to meet situations in spite of objective normality?

Besides anxiety neurosis there is a multiplicity of other functional disturbances of a psychological nature.

Take for example the category of hypochondriacs. There the disorder is characterized by a vivid sense of having one or more organs in a morbid state. The patient complains of a multitude of vague symptoms referable to one or several organs. Believing that a special organ is affected, he will observe its function from day to day or from hour to hour, and the most insignificant symptom will be interpreted by him as pathognomonic of some disease in a state of development. After having concentrated his thoughts on one organ for some time, he soon abandons it and takes up another organ in the function of which he finds disturbances. Digestive tract, genito-urinary apparatus, heart, nervous system—may all be taken up seriatim and become a subject of great solicitude by the patient. The heart particularly is very frequently considered to be at fault. Heart neurosis is a frequent accompaniment of the "anxiety state." While objectively no evidences of valvular trouble are present, nevertheless the individual will present sometimes palpitation, dyspnea, and dizziness, especially in connection with some emotional provocative agent. Whether those suffering from heart neurosis have actually some disturbance in the function of the ductless glands which per se is capable of producing the above symptoms, or whether the latter are the exclusive result of a mental condition which tends to produce physical symptoms, it is difficult to say. The fact nevertheless remains that neurotics do present heart symptoms which may disappear after the patient makes a recovery, although a temporary one. It stands to reason that in presence of a heart neurosis the individual thus affected will be constantly subject to a neurotic reaction which will prevent him from undertaking responsible work.

The neurotics may present psychic disturbances of another character. In phobias the individual may fear to cross or to find himself in an open space (agoraphobia) or in a closed space (claustrophobia). He may fear to be alone (monophobia). He may fear touching objects. Morbid doubt or indecision is another variety of neurosis; here the individual is never sure of the correctness of his acts. In obsessions the patient is unable to free himself from thoughts, ideas, or images (auditory or visual) which once have invaded his mind, and irresistible impulses may follow. In abulias the individual does not possess the power to do certain acts which he had intended to do. Here we find a deficient will. Should he try to overcome it he will be thrown into a state of anxiety and suffer intensely.

This brief description of some of the varieties of the tendencies and abnormalities of neurotics is sufficient, I believe, to give a general idea of the character and nature of the work that they may be expected to perform. There is a general common feature in this group of individuals, namely, that they are all fully conscious of their own disability and they are all constantly at work to overcome and repress the latter. They not only fail in their efforts but on account of the attempts at repression the mental abnormalities increase in intensity so that they become totally incapacitated; the more they struggle against their disabilities, the less they see themselves capable of undertaking a task assigned to them, their nervous energy is exhausted before they commence the work. The exhaustion is more mental than physical as the difficulties are more psychological than physical in their operations.

A little excursion into a deeper psychological explanation of the various psychic mechanisms underlying the abnormal manifestations of the neurotics will necessitate a discussion of the subconscious factors which possess the power of producing anxiety states, fears, obsessions, and other phenomena. The relationship of the subconscious world to the conscious ego is of no small importance when a true *modus operandi* for the abnormal psychology of the neurotic individual is sought for. Such a discourse would lead one to speculations which for the present would not answer the purpose of my address. My aim is to call attention to the necessity of personality study since we are confronted with the grave problem of individual capacity for warfare. To be conducted efficiently the latter must be conducted by efficient individuals. Persons who show psychopathic tendencies, persons who in civil life present evidences of ill-adaptation, are certainly poor risks for military work in time of war. We must have on the firing line the best and the most competent men who present the strongest guarantee of resisting a continuous physical and mental strain. This consideration is not exclusively an *à priori* judgment, but it is amply borne out by the experience of France and England. There the medical officers soon began to realize the error of admitting to the ranks at the front mentally unstable individuals. At first their difficulties were enormous and rapidly in very great numbers men were sent back with various psychoneurotic manifestations which rendered them absolutely unfit for actual service at the front. They had to undergo special treatment in special neurologic and psychiatric centers. It is needless to emphasize the material sacrifices and the difficulties of the respective governments created through an injudicious and indiscriminate selection of men for the most responsible activities at the front. Osler in a recent letter to the *Journal of the American Medical Association* (July 28, 1917, p. 290), speaks in strong terms of the disastrous results of carelessness in selecting recruits for the British Army. Let us profit by the unfortunate experience of our Allies in the selection of our men and let us avoid unnecessary casualties since the condition is largely preventable. Let us avoid a useless burden which neuratic recruits would necessarily throw upon our government engaged at the present time most seriously in solving most difficult problems. It has come to my knowledge that

various neuropsychopathic wards are being planned now for base hospitals at cantonment camps and psychiatrists from the base hospitals will be on duty at casualty clearing stations, also that psychiatrists and neurologists are now detailed to each of the American camps for the purpose of examining the troops in a systematic way in order to eliminate those who are found mentally unfit for war service. The desirability of such institutions is clear. But a question arises: Would it not be of a more direct and greater advantage to all concerned to decide the individual's fitness or unfitness at the time of enlistment instead of accepting the neurotic, of sending him to the camp and only then trying to find out his make-up. In war time, when so many complex problems arise almost daily, when the material sacrifices are enormous, when the government's responsibilities are unusually difficult, at such a time the simpler and at the same time more effective a method is devised, the more desirable it is. Proper recognition and immediate rejection of neurotic individuals before they are admitted to the military service would save considerable time and material sacrifices to the government. Immediate rejection of the candidates would obviate the necessity of clothing, feeding, and training them for an indefinite time. The present method adds an additional and unnecessary burden to the strenuous work of the authorities. Let the elimination of unfit recruits when found in the camps continue as mentioned above, but neurologists and psychiatrists attached to the home recruiting stations during the enlistment would greatly reduce the responsibilities of the military authorities in every possible way. Many of the specialists who are unable for one reason or another to perform active military service would gladly, I am convinced, render their assistance to the government and offer their services for special examinations. It is needless to emphasize the fact that by this method the work of the military authorities would be greatly simplified.

Recommendations for rigid exclusion of insane, feeble-minded, and neurotic individuals are self-evident, but it is particularly to be recommended that the act of excluding should be especially done at the home station during the enlistment. In case repeated examinations are necessary they can be made at home. When it is found necessary to obtain information from relatives concerning the previous health of the recruit it can be very readily done. In case a necessity arises to keep the individual under a more or less prolonged observation, the aid of one or more hospitals can be secured and the individual can be kept in bed under continuance study. Such a procedure can be carried out without any expense to the government, will save considerable time, and will relieve the army from the unnecessary burden which it is struggling to surmount. There is no doubt that individual physicians and hospital authorities will render such service to the country without any thought of compensation.

The home elimination method presents another advantage in that prolonged observation in a hospital will enable us to detect malingering and determine the diagnosis between a neurosis and malingering. While as a rule the differential diag-

nosis is not difficult, nevertheless occasionally we are confronted with some puzzling case demanding very careful discrimination. Kept in bed under constant and close observation of a psychiatrist and a nurse, confronted with facts gathered from friends and relatives, knowing well that he is subjected to expert examinations, a malingerer will soon break down and will be revealed in his true light. In presenting the recommendation of home examination and elimination of neurotics I intentionally omitted to point out the actual aggravation of their morbid symptoms by their transportation to camps, but under the circumstances the latter is a secondary consideration and must be ignored, as the welfare of the country is of paramount importance.

In connection with such a plan another thought suggests itself. Types, varieties, and subvarieties of neurotics are many. While all are unfit for actual military work at the firing line, some of them nevertheless are capable of performing some duties of a nature different from fighting. A good number of them could be utilized for work of a secondary character behind the firing line and thus release the men who are more fit to face the enemy. A large contingent of good and strong men will thus be added to the fighting force. The home examining psychiatrist after a profound study of the recruit's personality will determine the variety of the neurosis and the degrees of its development, and will thus be able to make suggestions and recommendations to the military authorities as to the kind of work a given neurotic individual could be assigned to. A systematic plan can be worked out by which the examining psychiatrist will familiarize himself with the multifarious duties incidental to military service in war time so as to be able to make the proper recommendation in behalf of those neurotic men who are not totally rejected. It appears to me that the military advantages and benefit of such a procedure will be of enormous assistance to our government with regard to time, efficiency, and expenditure.

To sum up, it is my opinion that apart from the consideration of the neurotic's welfare it will be a matter of expediency for the government to institute special examinations of each recruit at his home before he is sent to camp. For the reasons enumerated above more efficient examinations and accurate recommendations as to the individual's fitness for certain duties will thus be made. A great deal of labor, expense, and difficulties will thus be prevented.

1812 SPRUCE STREET.

THYROID DISEASE AND THE WAR.

By S. P. BEEBE, PH.D., M.D.,

NEW YORK.

THYROID disease as found in both groups, soldiers and civilians, will be markedly increased during the war. This statement is based upon the observations which have come to us from abroad where the intensity of the struggle has produced reactions as yet comparatively unknown to us, and upon experience gained in previous periods of intense hardship and emotion.

Knowledge of thyroid disease has increased so

much since there has been any previous big war that recognition of the true nature of conditions that have passed heretofore as neurosis is possible. The thyroid gland reacts instantly to a nerve stimulus by discharging its peculiar iodized protein into the circulation. This may be, as Crile and Cannon maintain, a defensive mechanism; the physiological effect is none the less produced. Students of thyroid disease need no long argument to be convinced of the close interdependence of intense emotion and the awakening into pathological activity of a hitherto quiescent thyroid gland. Not infrequently a so-called simple goiter, or colloid goiter, is whipped into sudden and dangerous activity by a single intense fright, or depressing sorrow. The activity continues long after the sudden shock which initiated it.

The writer several years ago had as patients four men who developed severe hyperthyroidism during their experiences in the army serving in the Philippine Islands. They were in excellent health on entering the army and could definitely date their trouble to a particular campaign. Later, at the time of the Kishineff massacre in Russia, patients who had been subjected to the horrors of this experience came to New York City with severe hyperthyroidism, the incidence of which they definitely dated from the fright and hardship then endured. The San Francisco earthquake produced similar cases. The writer saw three patients with this condition developed from the Triangle Shirt Waist Co. fire. These are a few concrete instances of the effects of intense emotion in stimulating the activities of a latent thyroid. In this connection it is interesting to quote from McCarrison's recent book on the Thyroid in Health and Disease, "a proportion of cases may be precipitated by some accidental circumstance, such as a train disaster, a fall from a horse, or by such circumstances as seduction, attempted rape, or the excitement and strain of war," and he cites among the factors which affect the thyroid apparatus, "Fright, mental distress and worry, business or social cares, unfortunate love affairs, violent emotion, and mental and physical exhaustion with loss of sleep such as occurs amongst soldiers in the trenches."

Factors of this kind affect a thyroid gland which has previously maintained itself within a normal range of size and activity, and prove potent indeed when certain types of enlarged glands are involved. The writer has repeatedly called attention to the marked effects which are sometimes seen in cases that have been classed as simple goiter as a result of factors of this sort. Some observers have maintained that glands of so-called simple type including therein small colloid goiters do not under any circumstances give rise to those severe toxic manifestations which we recognize as Graves' disease. Such a conclusion is due to faulty or limited observation and the writer is gratified to see that McCarrison agrees upon his point as he states that "Again Graves' disease may be superimposed on a goiter due to foetal or simple adenomata or it may commence in a thyroiditis due to some acute infection."

The medical observers abroad have noted that many cases of "soldier's heart" are in reality cases of hyperthyroidism and while there is not complete agreement on the part of the observers, the symptom

complex described corresponds with that of hyperthyroidism so closely that it does not appear that wrong interpretations have been made. Sir James Barr was the first to call attention to this condition and more recently Hurst has confirmed the observation and described the treatment that he employed. Our own army has as yet taken little part in the great struggle, but inquiry at the army hospitals has revealed the fact that the preliminary training in this country has already developed cases of hyperthyroidism among those who were accepted as physically sound. As the factors above cited become more conspicuously operative, the percentage is bound to increase.

The treatment of the hyperthyroid patient is not suited to the wards of a general army hospital. The number demanding treatment will assuredly be enough to warrant some special provision for their care. The recovery is slow, the disability will have been incurred in the line of duty, and the responsibility will be upon the government hospital service to provide suitable treatment. The treatment employed by Hurst does not seem to the writer entirely suited to the condition. Opium for mental restlessness and belladonna to check the thyroid and adrenal secretions is a form of therapy that has been largely discarded in civil practice. Suitable quarters and treatment are necessary if these men are to have what they deserve.

The civil population will suffer from somewhat similar emotional disturbance. The wives, sisters, sweethearts and mothers of the soldiers have had some foretaste of what is to come and unless all previous experience is to be contradicted, the incidence of hyperthyroidism will be markedly increased. The recognition of this condition during recent years has constantly improved, yet even now too many cases are unrecognized and poorly treated.

It is to be presumed that unusual care has been exercised in the physical examination of the men accepted for service in the army and navy, yet the reports from the army hospitals in this country show that men are already being admitted who have well marked conditions of hyperthyroidism. In view of such conditions it is to be presumed that the proportion will be increased as the provocative factors become more intense. The disability having been incurred in the line of duty is one which should be cared for by the medical service. As far as the writer can learn no special provision has been made for this class of patients. They need and deserve such care. It is to be hoped that a policy of wholesale operation, which has been so popular in recent years in this country, will not be adopted for such cases.

The thyroid patient needs special care quite as much as the tuberculous patient, or those having injuries and deformities requiring orthopedic correction. The pressing need for action in other fields has been great, without question, but here is a field also already incapacitating the country's soldiers and in some fashion it must be met.

The cases occurring in the civil population will be cared for in the usual way by the civilian physicians, but the organization of the nation's resources for war signifies attention to detail. A soldier or civilian invalided by hyperthyroidism is quite as much an ineffective as though rendered helpless by

a bullet wound, with the added burden of requiring a longer time to effect recovery. The early stage of the disease is the period most easily remedied. The early recognition of thyroid disease and its proper treatment is therefore a part of the great struggle.

417 PARK AVENUE.

EXAGGERATED VIEWS ABOUT THE CON- TAGION AND OUTCOME OF PUL- MONARY TUBERCULOSIS.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

THE great evil at the present time, connected, as I believe, with the growth of knowledge and modern specialism, is morbid introspection, which exists in many persons.

Witness what has occurred in regard to tuberculosis. Consumption has become a great dread to the individual and to the community. It is only necessary for a few physical signs in the chest to be noted by a practitioner and immediately there is a shake of the head, or a doubtful tone of voice, and very soon the patient is obliged to be over-careful in every way. With a slight cough and expectoration added, the sputa are examined microscopically. If perchance a few tubercle bacilli are found, nothing short of a sanatorium is advised, or insisted upon. Then, what results? A home or business broken up and imperative exile of many months follows. This is done to help cure the individual and protect the public. The individual is not infrequently rendered unduly morbid as a consequence and a disease which is often thoroughly curable with a little time, fairly good surroundings and a few properly selected medicines, becomes a badge of martyrdom.

As to danger to the community. In my judgment, it is very slight, especially from patients at the first stage, or even the second stage, of the disease. Later, when pulmonary cavities, profuse expectoration and all the symptoms and signs of a grave general condition are present, it is different. Then, careful and special precautions should be taken. Even so, exaggerated fears should not be allowed.

The sputa, of course, should always be properly disposed of according to established rules, and the patient should not cough where others are present, without protecting his mouth with his handkerchief. Further, he should have a room to himself for sleeping and he should be careful to wash his hands when soiled and to have his own towels and table utensils.

But as to innumerable rules of government to protect others from the disease, or to be helpful to himself, these I do not consider important from a broad and sane viewpoint. If tuberculosis were very contagious it would be more widely transmitted everywhere: in street cars, in the subway, in theaters, churches, and, indeed, wherever crowds collect and there is insufficient fresh air. I, for one, am convinced it is not true, although apparently hallowed by modern teaching.

Money and work without stint or limit have been used to build sanatoria and help cure this disease. Have the results thus far obtained proven satisfactory? To my mind, no, if statistics are properly

interpreted. On the other hand, let it be understood that I uphold absolutely every effort to promote cleanliness and decent living for all, not merely for the tuberculous. This is progressive work and is the best we can do for general and individual health and well-being. To build up bodily vigor in every way is to destroy, as far as may be, inherent physical weakness, so that tuberculosis cannot take root or grow for long. The disease soon becomes self-limited or neutralized, and there need be no fear, usually, of its ultimate outcome. True, in some instances the bacilli may still be present in the sputa, but they are then the scavengers rather than the "fons et origo" of the disease.

At all events, adjoined to them, is no longer the poison that has once been there, even though the habitat is the same. There are exceptions, as always in medicine. We must admit there are some persons who cannot live in the city. They must live in the country, if they would enjoy tolerable health and stay the march of disease. Again, there are persons in whom when the disease has once taken hold it goes from bad to worse more or less rapidly and despite our efforts to check its onward and fateful march. This is notably true to-day, because we have to a large extent lost our faith in time-honored and, to me, useful medication.

Latterly, I am glad to add it has been proven by reliable statistics, that results obtained in a model "home hospital" are quite equal to those secured by sending patients to sanatoria, thus breaking up family ties and business affairs and causing great mental distress, which surely does not help "a cure."

In the advent of the "home hospital" is found an additional plea for healthful homes for the poor, and in this way to prevent tuberculosis and not simply to cure it when it is already present. The managers of the Association for Improving the Condition of the Poor in New York have established in their "home hospital" a model to be followed by all who wish to improve tenement-house conditions. I regret that at the present time we have no "home hospital" for our ill-colored citizens.

The summary, taken from the last "Home Hospital" report, is most instructive. I append it here.

"1. Since, so far as is known, no individual not previously infected with tuberculosis has developed symptoms of the disease while a resident at the Home Hospital, it would seem that under proper medical and nursing supervision tuberculosis may be treated in homes without serious danger of infecting well members of the family.

"2. Since the condition of the children has been so greatly enhanced the Home Hospital affords treatment at least the equal of preventorium care. Moreover, adequate corrective work is accomplished.

"3. Since most of the incipient and many of the moderately advanced cases have been restored to health the medical results compare most favorably with those of the best sanatoria; and finally

"4. Since so much has been accomplished in the social and economic rehabilitation of the families, the medical and economical practicability of the Home Hospital method of treatment seems to have conclusively demonstrated its real practical value in the treatment and control of tuberculosis in urban communities.

STERILIZATION AND PURIFICATION OF WATER WITH ISOTONIC SODIUM HYPOCHLORITE SOLUTION.*

(WITH THE NEUTRALIZATION OF THE WATER BY PEROXIDE OF HYDROGEN.)

BY WILFRED G. FRALICK, M.D.,

NEW YORK.

THE writer has been experimenting since 1901 with hypochlorites of various kinds for both surgical and sanitary purposes. About 1903 the isotonic sodium hypochlorite solution was perfected by me for surgical work and has been used in various concentrations for treatment of superficial and deep wounds, for introduction into closed cavities, and, with proper technique, for intravenous infusion. Its value has been repeatedly demonstrated for the dissolving of infected blood clots and necrotic tissue.

The application of isotonic sodium hypochlorite solution to water purification is of long standing and has been recommended by me because of the purity of the reagent and its high concentration of oxygen-ions (0 Cl). The method of preparation,† bactericidal action, and phenol coefficient have already been published (*Medical Times*, July, 1917) and it remains now in this connection to set forth some of the recent work which I have done on the application of this reagent to the disinfection of water in containers, such as the portable emergency outfits used in the present campaign by the United States Army.

Stability.—I have been able to stabilize the isotonic sodium hypochlorite solution by the addition to it of a small quantity of potassium permanganate. This method of stabilizing hypochlorites seems to depend largely on the deflection of the photochemical rays of light by the pink color of the permanganate solution. Recently the technique of preparing the Carrel-Dakin fluid has been modified to include my method of stabilizing hypochlorites.

Strength.—A typical series of tests by the author on the comparative bactericidal powers of phenol and isotonic sodium hypochlorite solution will indicate the strength of the latter reagent for water purification.

	Isotonic Sodium Hypochlorite Solution	Phenol
<i>Streptococcus pyogenes</i>	1 = 2000	1 = 40
<i>B. dysenteriae</i>	1 = 2500	1 = 50
<i>B. diphtheriae</i>	1 = 2700	1 = 60
<i>B. typhosus</i>	1 = 2000	1 = 45
<i>B. coli-communis</i>	1 = 3500	1 = 90
<i>B. suispestifer</i>	1 = 2500	1 = 60
<i>Microspira cholera</i>	1 = 2500	1 = 70

Time exposure, 5 minutes.

The phenol coefficient with various organisms ranged between 60-120 in many series of tests.

Manheimer‡ conducted tests on this solution

*From Dr. Fralick's Private Research Laboratory.

†The method of manufacture which has been published, with slight modification could be elaborated for industrial application. Careful regard for technical details is of great value, if the production of chlorates and other harmful byproducts is to be avoided.

‡Research Laboratory of the Health Department of the City of New York.

with water heavily infected with sewage organisms and obtained 99.6 per cent. purity using a 1 per cent. solution of the chemical in 8,000 parts of water. This is equivalent to 1 part of chemical in 800,000 parts of water, and when we consider the large amount of heavily contaminated water he was treating, the results must be considered as exceptionally good.

Neutralization.—At the present time the disinfection of water in emergency outfits (Lister bags) using chloride of lime, while effective in water sterilization only if an excess of chemical be used is objectionable on account of the taste and slightly poisonous character of the water resulting. It has been the writer's contention for years that the present method of calcium hypochlorite water sterilization adopted by the United States Army, should be discontinued in view of the injury produced by the ingestion of the excess chlorine and other products in the water and in view of the fact that the troops avoid drinking it wherever possible. Where the calcium hypochlorite is still used, it becomes necessary to make the water at least palatable by neutralization of the excess hypochlorite according to the method below. The addition of small quantities of isotonic sodium hypochlorite solution is entirely effective as a disinfectant and its presence in the water, while noticeable when in excess, is not injurious upon ingestion.

The writer* has proposed and demonstrated the use of two chemicals for water purification in emergency outfits (Lister bags), so as to produce a safe water, entirely free from objectionable tastes and odors. To do this he has recommended the use of the isotonic sodium hypochlorite solution as a disinfection and the neutralization of the excess NaOCl by peroxide of hydrogen $\text{NaOCl} + \text{H}_2\text{O}_2 = \text{NaCl} + \text{H}_2\text{O} + 2\text{O}$, while the effectiveness of this method had been repeatedly demonstrated at this laboratory, field tests under army conditions were conducted and the testimony of a number of sanitary experts obtained. There was a unanimous opinion expressed that water neutralized with the H_2O_2 was entirely free from any objectionable or even noticeable taste or odor, while bacterial tests demonstrated its freedom from microorganisms.

Conclusions.—1. In view of the disagreeable and probably injurious qualities of water disinfected with calcium hypochlorite, in emergency outfits (Lister bags), and in view of the fact that troops avoid drinking this water, we recommend its discontinuance.

2. Water can be sterilized with small quantities of isotonic sodium hypochlorite solution, and subsequently neutralized by the addition of peroxide of hydrogen.

3. Water treated with isotonic sodium hypochlorite solution and neutralized with H_2O_2 is sterile, free from taste, and absolutely palatable.

4. This system of water purification as presented to the Surgeon General of the U. S. Army is efficient, economical, and practical.

33 EAST SIXTIETH STREET.

*The writer, in a personal visit to the office of the Surgeon-General, explained his method of preparation of the isotonic sodium hypochlorite solution and offered his services to assist the Government in the production of the chemicals necessary for use in the army.

Medicolegal Notes.

Workmen's Compensation — Idiopathic Conditions Causing Injury.—The California Workmen's Compensation Act, like practically all the others, allows compensation to the dependents of an employee only where the proximate cause of his death is a personal injury sustained by an "accident arising out of and in the course of his employment." It is held that the death of an employee engaged in the erection of a building upon a scaffold 30 feet above the ground, properly guarded by a rope along its outer side, as the result of an epileptic fit in which he fell down on the scaffold and rolled over the edge, was not within the statute; the question whether the injury arose "out of" the employment not depending on the height from which the employee fell or the extent of the injury.

Prior decisions in similar cases are for the most part to the same effect. In *Van Corder v. Packard Motor Car Co.* (Mich.), 162 N. W. 107, an employee, while at work on a scaffold 6 feet in height, was seized with an epileptic fit, which caused him to fall off the scaffold to the floor, whereby his skull was fractured and his death ensued. It was held that the fit was the direct and only cause of his injury, and no compensation was payable. In *Butler v. Burton on Trent Union*, 3 B. W. C. 355, the deceased, while on duty, was sitting at the top of a stairway. A fit of coughing, due to the fact that he was afflicted with tuberculosis, came on and made him giddy, causing him to fall down the steps. From the injuries resulting therefrom he died in a few days. It was held there could be no recovery. In *Collins v. Brooklyn, etc., Co.*, 171 N. Y. App. Div. 381, the deceased, while at work, fell to the ground in a swoon due to heart disease, and thereby received the injury which caused his death. It was held that it did not arise out of the work. The court drew a distinction between cases of this character and those where the accident, though partly caused by the idiopathic condition of the employee, is due in part also to the overexertion of the employee in performing his work, or to the lack of proper safeguards against the ordinary dangers of the place of work, or to the nature of the work, or the appliances furnished with which to work, the injury being sometimes greater because of his idiopathic condition. In these cases the injury is held to arise out of the employment. An example of these cases is *Fennah v. Midland, etc., Ry.*, 4 B. W. C. C. 440, where the deceased, an engine driver, was tightening a nut in the engine and suddenly fainted and fell. The court, from the evidence, was of the opinion that his fainting fit was brought on by the work, and held that the injury arose out of the employment. Where the idiopathic condition and the employment are each contributing causes of the accident the employer is liable, but not where the idiopathic condition is the sole cause.

The only case to the contrary is *Wicks v. Dowell*, L. R. [1905] 2 K. B. Div. 225. The deceased was seized with an epileptic fit while standing on a wooden stage in a ship, close to the edge of a hatchway opening into a hold, and while guiding the descent of a bucket into the hold by means of a long pole and as a result he fell into the hold and was injured. The award was made. But this case stands alone and is contrary to the later decisions arising in England under the same law. *Brooker v. Industrial Accident Commission*, California Supreme Court, 168 Pac. 126.

Accidental Injury Under Workmen's Compensation Act.—The Michigan Supreme Court holds that where an employee who had had heart trouble of long standing died as the result of heavy physical labor which ruptured an auricle in his heart, there could be no award under the Workmen's Compensation Act for his death on the theory that it was accidental, it appearing that the work was done as he intended and agreed to do it, and that the death resulted merely from the strenuous labor.—*Stombauch v. Peerless Wire Fence Co.* (Mich.) 164 N. W. 537.

Workmen's Compensation Act—"Accidental Injury."—The Texas Court of Civil Appeals holds that where the lifting of a can of paint caused a blood vessel in a servant's lungs to burst, there was an "accidental injury" within the meaning of the Workmen's Compensation Act, and it was immaterial that it had burst before, but had healed over and might burst again.

Military Medicine.

THE CARE OF DIGESTION FOR THE SOLDIER.

BY MAX EINHORN, M.D.,

NEW YORK.

CAPTAIN, M. R. C., U. S. ARMY; PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

DIGESTION deals with the food intake and its complete assimilation. The aim of the soldier is efficiency and a capacity for strenuous work, without injury to the system. In order to accomplish this, greater amounts of food than normal must be taken. The demands made on the soldier's digestion will be correspondingly greater.

The usual principles for the care of digestion can be briefly summarized as follows: Regularity in taking meals, eating leisurely, diversity of foods, frugality, work and rest proportionately divided. Neither overfatigue nor too much leisure should be allowed to occur.

Although these maxims pertain to all individuals alike, the soldier included, and should be followed, whenever feasible, the army-man is so placed that he frequently cannot obey these laws.

For this reason it appears appropriate to consider how best to act in these precarious conditions of a soldier's life.

I. *The Food Problem.*—A greater diversity of foods is usually impossible in camp life. The soldier will therefore do well to partake of every article of food offered him, in order to avoid a diet that would be too one-sided.

As a rule he should endeavor to partake of the entire portion of cereals, vegetables and fruits allotted to him and of meat as much as he desires. Peas, beans and lentils contain a considerable quantity of protein and should be indulged in liberally. Fruit-jellies and jams are useful when fresh fruit cannot be had. The foods usually being concentrated, it is important to have tea, coffee, or cocoa, with milk and sugar at each meal, also good drinking water. The latter should be taken, one to two glassfuls (according to the requirements of the body; more in hot weather than in cold) at each meal.

II. *Rules for Meals.*—(a) When activity is known; (b) For exceptional and undeterminable work.

(a) The soldier should lead as regular a life as is compatible with his duties. Meals should be taken at regular intervals, if possible, at about the same time every day. Some time should be spent in consuming a meal, eating leisurely neither too fast, nor too slowly. The morning meal should be the lightest of the three meals. A short period of rest (spent in conversation, smoking, etc.) after meals is advisable. After the evening meal, this period of leisure should be extended over a longer time. Anything that contributes to the amusement of the individual will be of help toward a healthy digestion. Playing of games or listening to music and story telling is, therefore, highly commendable.

(b) When there is a hurry call and the mealtime must be considerably shortened, the soldier will do well to partake of a rather small quantity of light foods. A cup of warm (not hot) coffee or tea and

bread and butter or a sandwich, or porridge will best serve the purpose. Hot dishes and meats are not appropriate at such hurried occasions. The reason why larger meals and heavy foods are here not desirable is because the soldier then has no time, nor the desire to masticate the food properly. A heavy meal faultily ingested may easily lead to bad consequences.

Similarly a meal which must be taken after exhausting marches or other over strenuous work or after prolonged fasting, should be of a light character and of a rather moderate quantity. After a period of rest the next meal may be taken in full amount and in the usual manner.

III. *Urination.*—Passing of urine should be done at regular intervals, if feasible. Empty the bladder when arising and retiring, also before starting out for a prolonged march or other important steady work.

IV. *Defecation.*—Attempt to have a movement of the bowels when arising. If unsuccessful do not worry about it, nor think of it. Whenever there is an inclination for defecation, nature's call should be obeyed; otherwise wait until the next morning. Drinking of water, ingesting larger amounts of fruits, salads, jams and vegetables will greatly contribute toward a regularity of the bowel movement.

V. *Rest.*—The soldier being subjected to strenuous work, must also have periods of rest. This applies here in a still higher degree than in ordinary life. Efficiency is impossible unless there is complete recreation after fatigue.

VI. *Sleep.*—Sleep is the acme of rest. In this state the muscles, nerves, and brain cells are completely relaxed, and the blood stream washes out and carries away all waste products which had accumulated during the period of work. Eight hours' sleep should be allotted, unless in exceptional straits, when this period may be somewhat shortened.

Rest and sleep are essential factors in keeping the digestion in good trim. For this reason as much attention should be paid to these two factors as to the other items regarding nutrition.

At first glance it appears rather impossible for a soldier to take good care of his digestive apparatus. For many of the conditions prevailing in army-life are necessarily contrary to hygiene. In reality, however, the soldier quickly accommodates himself to the new conditions, and his digestion is as good as in civil life. It is a great blessing of nature to have fitted our organism with a great deal of elasticity, so that it can adapt itself to the most unfavorable states.

In observing the rules outlined, good digestion will be considerably enhanced in the soldier.

20 EAST 63D STREET.

Ear Injuries in the War.—In an article in *The Journal of Laryngology* for November, 1917, Major W. Sohler Bryant of New York calls attention to the large number of aural injuries received by soldiers in active service at the front. The proportion of these injuries is much greater than in previous wars by reason of the increase in large guns, shells, mines, bombs, grenades, etc., together with the longer exposure to rapid-fire arms. The loud detonations rupture the tympanic membranes

and cause hemorrhage, ecchymoses, and molecular disintegration of the ear apparatus. Continued irritation of the ear apparatus by less violent explosions causes a molecular change and nutritional impairment, resulting in a dry inflammation of the ear apparatus. Deafness and vertigo are common effects of "commotion" and "shell shock," of whatever kind or nature. At the front, the susceptibility of ears to damage is increased through obstruction of the nares, the pharynx, and the Eustachian tubes. The presence of nutritional disturbances, otosclerosis, "dry catarrh," calcification, and fibrosis renders the ear mechanically more delicate and susceptible to injury.

Dr. Bryant divides the nature of the injuries of the ear and their complications into three categories: (1) Rupture of the tympanic membranes. (2) Complications of ruptured tympana; (a) acute or chronic suppuration of middle ears; and (b) mastoiditis, mastoid abscess, and its complications. (3) Commotion of the viii cranial nerve apparatus. (The cochlear branches always suffer, the vestibular branches less frequently.)

Although among the troops the onset of ear diseases is naturally more rapid than it is in civil life, convalescence is, by way of compensation, often considerably shorter than in civil life. The clinical histories of many ear patients show the rapid (a few weeks) sequence of degenerative, dry inflammatory conditions of the middle ear following ear injury at the front. With appropriate care, however, ruptured tympanic membranes heal without suppuration, and with restoration of function in five to twenty-one days. Convalescence is considerably shorter than the course of middle-ear suppuration is in civil practice, and averages about twelve days. Uncomplicated middle-ear suppuration among the soldiers yields very quickly to dry treatment, probably because the condition is primarily traumatic, and is not due, as in civil practice, to an underlying pathological state.

As to treatment, Dr. Bryant says that the treatment of ruptured tympanic membranes and the prevention of complications is directed to the encouragement of spontaneous repair, which is best secured by the prevention of infection and suppuration. The care of the perforations should be aseptic, dry treatment, removal of moisture in the meatus by wiping, insufflation of sterile boric acid powder, and plugging of the meatus with sterile absorbent cotton painted with collodion. The dressing should be repeated sufficiently often to secure the desired protection against suppuration. The treatment of suppurating middle ears and consequent complications is the same as is required in civil practice. The good results of treatment and operative intervention are surprisingly quickly obtained among the soldiers, and are very satisfactory.

Volhynia Fever.—This affection was described early in the war as occurring in Volhynia. Later it was comprehended under quintan fever and recognized on other fronts. It is a new kind of infection which may have sporadic or epidemic incidence. Fever and pain last for one or two days and a new crisis occurs every five to seven days. It must therefore be distinguished from fever which runs its entire course in five or seven days. It is conveyed from man to man by the body louse. Quintan fevers have represented a

type of malaria since the time of Hippocrates and the new malady was regarded originally as of malarial nature and later as a form of influenza (trench influenza). Numerous designations have been proposed to distinguish it from other trench fevers. It has now been seen on all of the chief fronts save the British-German. Its occurrence in Italian sectors is responsible for the publication of an article by Ceconi in *Il Policlinico* for November 18 (Practical Section). Its actual cause is probably a protozoan carried, as already stated, by the body louse. The blood of patients can be made to infect guinea pigs. In cases in which animal tests were negative the disease has been shown to be inoculable in man. Blood was injected into the buttocks and the incubation period was found to be 21-23 days. When louse transmission was made possible infection of well men by infected men occurred sooner or later, but the interval was long, some six months, showing that time is an important element in the transmission of the disease. The presumption that a spirillum is the cause of the disease is strong and several observers claim to have found spirochetes in the blood. Riemer even succeeded in cultivating one in inactivated human serum. The significance of such a find is weakened by numerous other positive results obtained by other men. This muster of inharmonious discoveries is also seen in connection with exanthematous typhus, with which affection volhynia fever has other points in common.

It has been asserted in fact that volhynia fever is only a mild, abortive form of typhus, but such a view is opposed by the fact that while one attack of typhus protects the subject from further infection, volhynia fever readily recurs after a space of six months. Furthermore, volhynia fever bears no clinical resemblance to mild typhus nor what is known as Brill's disease. Shin ache is a very prominent symptom in volhynia fever and may be the only symptom of an access, while fever and tibialgia together are the prevalent manifestations. Diagnosis is made chiefly by the quintan course and the chief conditions to be excluded are malaria and relapsing fever, in both of which positive blood finds should be obtainable.

The entire course of the disease is four to five weeks on the average, while the period of convalescence is two to three weeks. Soldiers return to the ranks in from seven to eight weeks after the beginning of the infection. Although it is nominally a benign affection some writers assert that by reason of certain sequelæ, chiefly segmental hyperesthesia, only 18 per cent. of the men are left fit for active service. But such an experience is quite exceptional. There is no specific, spirillocide remedy, and only drugs like aspirin or pyramidon render transitory service. Anti-louse measures should prevent the development of the disease.

Plans for Rehabilitation of Disabled.—Comprehensive plans for the vocational training of disabled soldiers and sailors as well as of civilians employed by private firms, have been outlined in a report from the Federal Board for Vocational Training recently submitted and an appropriation of \$10,000,000 has been asked. It is calculated

that 100,000 men will be disabled during the first year of the war of which 20,000 will require total or partial reeducation. The Canadian estimate shows that 10 per cent. of the men sent overseas return physically unfit for military duty.

Navy Again Appeals for Eyes.—The Navy Department has again sent out an appeal for more binoculars, spy-glasses, telescopes, sextants, and chronometers. The recent appeal brought some 6,000 glasses of various kinds, but the supply is as yet wholly inadequate. Glasses may be sent to Assistant Secretary Roosevelt, Navy Department, Washington, D. C.

Deaths and Sick Rate in Army Camps.—The sick rate in both National Guard and National Army camps for the week ending January 25 shows a slight increase over that of the preceding week. The non-effective rate for the National Guard was 50.4 per thousand as compared with 49.1 for the preceding week. The non-effective rate of the National Army was 53.9 as compared with 51, and the hospital admission rate was 39.6 as compared with 36.6. There were 81 deaths in the National Guard camps, compared with 66 the preceding week. Of that number 47 were due to pneumonia. Deaths in the National Army numbered 108, against 149 for the previous week, 71 being due to pneumonia. Camp Wheeler, Georgia, showed the highest non-effective and admission rates. There was a slight increase in measles at Fort Logan, Texas, with a few new cases of this disease in other camps. Camp Doniphan, Okla., and Camp Wheeler showed considerable increases in the number of pneumonia cases. Among the National Army camps the highest non-effective and admission rates were at Camp Travis, Texas, where mumps prevails. There was an increase in meningitis in all of the army camps. Scarlet fever is declining at camps Sherman and Pike, but increasing slightly at Camp Lewis, Washington. Camp Wadsworth is under quarantine, following a conference of United States Public Health Officers and civil and military authorities, on account of cerebrospinal meningitis, there being seven cases in the camp. The camp of the United States Ambulance Corps at Allentown is under quarantine on account of the prevalence of measles.

Red Cross Appropriations.—An announcement from the Headquarters of the American Red Cross on January 28 shows that the appropriations of that organization to cover the period up to April 18, 1918, for relief work in France, will amount to \$30,519,259. In addition to this amount \$768,649 has been appropriated for the purchase of supplies in the United States which will later be shipped to France.

Deaths in the Service.—LIEUT.-COL. JOHN D. MCCRAE, Chief Medical Officer in Brigadier General Morrison's command, and author of the war poem, "In Flanders Field," died recently of pneumonia, in France. He was a graduate of the University of Toronto, in the class of 1898, and was 46 years of age.

LIEUT. FRANK HANBIDGE, Medical Reserve Corps, U. S. A., died of pneumonia in France on January 31. He was 30 years old and was a graduate of the College of Physicians and Sur-

geons, New York, in 1916, afterward serving as interne in the Kings County Hospital. He was a son of Dr. William B. Hanbidge of Ogdensburg, N. Y.

Three Hospitals Damaged by Bombs.—A dispatch from Rome states that on the night of January 26 Austrian air raiders dropped bombs on hospitals in Trevisa and Mestre, causing great material damage to three hospitals in Mestre and wounding some of the attendants.

Tetanus Antitoxin in Frost-bite.—Chavasse, in a recent communication to the Société de Chirurgie de Paris emphasizes the importance of employing preventive injections of tetanus antitoxin in all the complications of frost-bite with phlyctenulae, ulcerations, or gangrene. The first dose should be 20 to 30 c.c., and, according to the advice of Raymond, the injections should be repeated, in doses of 10 to 15 c.c., in all these cases, at intervals of a week until recovery.

Campaign for Army Nurses Successful.—Surgeon-General Gorgas has reported to Secretary Baker that, as a result of the special campaign for the enlistment of army nurses (as announced in the MEDICAL RECORD of January 12), the deficiency in that branch had been made up. Instances in which soldiers in camp hospitals had to endure unnecessary discomforts have been traced in nearly every case to the fact that the War Department had failed in its efforts to obtain enough trained nurses and hospital attendants to permit the assignment of an adequate number to each camp. General Gorgas has recommended additional buildings at the camps for housing the nurses.

U. S. Army Hospitals at Vichy.—M. Justin Godart, the French Under Secretary of State of Medical Service, has placed at the disposal of the American forces ten hotels at Vichy, the well-known watering place of Eastern France. The Americans plan to install five hospitals in the hotels. Seven thousand beds have been requisitioned.

Fight on Tuberculosis in the Army.—The National Association for the Study and Prevention of Tuberculosis estimates that from 1 to 3 per cent. of the men being examined in the different training camps of the new army are being dismissed on account of tuberculosis. At the lowest estimate this would mean 100,000 tuberculous men in the first 10,000,000 classified for service. In order to obtain a wider support by prominent physicians and public spirited laymen in its effort to check the spread of this and other diseases in the army, the National Association began a thirty-day campaign on February 4 for 5,000 new members. The present membership is 2,500. The appeal for membership is to doctors and philanthropists and not to the general public.

Christian Scientists as Chaplains.—Secretary Daniels of the Navy has appointed Richard J. Davis of Boston, a Christian Scientist, as a chaplain. Mr. Davis has been commissioned with the rank of lieutenant, junior grade, and has been assigned for duty, temporarily, at the Boston Navy Yard. He is said to be the first Christian Scientist to be appointed as a chaplain in the navy, although two have already been appointed in the army.

THE CLASSIFYING MANIA IN PSYCHIATRY.

It is easy to sympathize with the pleasurable excitement of the bewhiskered professor who, after the successful pursuit of a specimen of the order *Lepidoptera* across a field, is able to identify it as a *Callicore clymena* Hübner; having once settled its status forever, whenever it occurs to him again he has a comfortable sense of completeness—he knows what it is, and there are no annoying loose ends in his mind about it. Just so the physician feels vaguely annoyed when a patient's disorder fails to fall into any exact class and he is obliged to think of the case as probably this, perhaps that, or possibly the other thing. Such a state of mind is exasperating to the man whose principles forbid him to leave anything in doubt, like the crumpet-man told of by Sam Weller.

The possessor of this type of mind should never make psychiatry his specialty, for each mental case is a law unto itself and while we have patients who are definitely precox, or manic, or paretic, we have also the "classes allied to dementia precox," the "manic-like reactions," the constitutional psychopaths, the syphilitic pseudoparetics, and the vast army of borderland cases. To be sure, labelling experts in all ages have had their fling at mental science, the chief modern exponents of this art being the French, of whom Ziehen may be taken as the type. Here mental disease is split up into groups, divided into sections, classified by course, prognosis, and symptoms and, in short, subdivided and re-divided and re-redivided until each patient becomes himself a class.

Kraepelin, with his wealth of experience and breadth of view, gave expression to a great truth when he said that the psychiatrist should be content if he is able to classify accurately approximately one-half of his cases. More important to his mind are the problems of prognosis and treatment. Certain aspects of the symptomatology and of the patient's individual psychology indicate that he will probably deteriorate rapidly, or that he will recover, although with a great probability of future attacks, or that he will recover permanently under favorable circumstances. All these things are extremely important in dealing with the patient and his relatives, while the mere inscribing of a case in a neat book

somewhere as "Psychosis associated with organic brain disease; cerebral arteriosclerosis; paranoid state," however gratifying to the systematic mind, is less important than knowing the patient's make-up, the depth of the reaction to the materials of his psychosis, etc.

Let the psychiatrist, then, spend less time in debating fine details of diagnosis, which after all may have little or no bearing on the patient's welfare, and more time to the histopathology, the psychology, the endocrinous glands, psychotherapy, ergotherapy, and other vital problems.

METHYLENE BLUE IN THE DIAGNOSIS OF ACUTE PERFORATING GASTRIC AND DUODENAL ULCERS.

IN cases where a good history cannot be obtained (and sometimes even in spite of it) it is often difficult to make a differential diagnosis between acute appendicitis and acute perforating gastric or duodenal ulcer. This is particularly true when cases are brought to the hospital with evident peritonitis and with marked tenderness in both the appendical and epigastric regions. Owing to the tendency for any fluid which escapes from a duodenal perforation to follow the path to the right iliac fossa, peritoneal irritation in the region of the appendix soon becomes a prominent feature and operation may be, and often is, based upon a preoperative diagnosis of appendicitis. The appendix may be found to be practically normal, or it may be found acutely congested, is removed and the wound closed with or without drainage under the impression that all the pathology has been taken care of; and still a perforation of stomach or duodenum may be present and require reoperation or is discovered only at autopsy.

In order to determine whether or not perforation of the stomach or duodenum is present, and to aid in the localization of the perforation if one be present, H. L. Baker (*Surgery, Gynecology and Obstetrics*, December, 1917) conceived the idea of administering a small amount of methylene blue by mouth, since with perforation of either the stomach or duodenum any fluids which leaked into the peritoneal cavity would be colored by the dye and could not be mistaken for ordinary peritoneal exudates and transudates. In one case in which the differentiation between acute appendicitis and gastric or duodenal perforation was difficult this resource was employed. About two hours before operation the patient swallowed 3 grains of methylene blue dissolved in 1 ounce of water. At operation the appendix was found to be normal and the incision was prolonged upward. The peritoneum was inflamed and discolored a bluish green hue. Traction was made on the greater curvature of the stomach, when a fine stream of bluish fluid was seen to spurt out through a small perforation on the anterior surface of the duodenum. This directed attention to the site of perforation. In this case convalescence proceeded

satisfactorily until the sixth day, when signs of pneumonia developed and the patient ultimately died, autopsy showing bronchopneumonia in the dependent portions of both lungs.

Baker states that he has been unable to find in the literature any reference to the use of bland coloring matter, such as methylene blue, as an aid in the diagnosis and localization of acute perforations of the stomach and bowel; also that the method is extremely simple, devoid of danger, and appears to possess several features of practical value. He considers that chief among these are the ease and rapidity with which the diagnosis and site of perforation can be determined, and with minimal amount of shock attendant on the handling of the viscera. He advises that the methylene blue be given 30 minutes to 1 hour before operation.

The method seems worthy of trial, in selected cases at least, for it is often difficult to locate the point of perforation without undue traumatism, loss of time, and danger of spreading infection, all of which add to the amount of shock and render the prognosis more grave; and it would hardly seem that the ounce of methylene blue solution which is introduced into the stomach could do any additional material damage.

THE VENEREAL DISEASE QUESTION.

It is a well-known fact that venereal diseases are very prevalent in the countries of Europe at war, and that they are the cause of a great deal of disability and inefficiency among the fighting forces. From the strictly military point of view, then, it is most essential that such diseases should be checked and controlled, for it is the most fit and efficient army that will win. From the civilian standpoint, the solution or partial solution of the venereal problem is even more important, and this aspect of the situation will present itself in a more menacing light after the war, when the soldiers return to their homes.

The gravity of the venereal problem is recognized by the medical profession, and Surgeon-General Blue of the Public Health Service has taken an important step looking to the control of these diseases. It is stated in Public Health Reports, January 4, 1918, that the surgeon-general considers that the control of venereal infections in connection with the prosecution of the war constitutes the most serious sanitary problem now confronting the public health authorities of the United States. It is pointed out that it is evident that the prevention of venereal infections in the military population is largely dependent on the degree with which these infections are prevented in the civil community, and that this imposes upon the civil health authorities the duty of forcefully attacking the venereal problem upon the basis of the control of communicable disease. With this end in view, an outline of the proposed plan of campaign has been forwarded to the health authorities of the various States.

Attention is drawn to the fact that the Public Health Service, in cooperation with the Red Cross and the Medical Department of the army, is establishing venereal clinics in cities in immediate contiguity to the army cantonments. Stress is laid on the thorough education of the general public to the end that the disease group will be considered in the same light as are the other communicable infections. The memorandum drawn up by Surgeon-General Blue and sent to Public Health officers contains some drastic recommendations. The greatest obstacle in the way of controlling venereal disease is the difficulty of tracing infected women. Public prostitution can be controlled, but when rigid prohibition is placed upon public prostitution clandestine prostitution generally flourishes, and it is the infected women who engage in this form of the traffic who are the chief means of spreading infection, and who, as the law stands now, are almost impossible to locate. In the memorandum referred to suggestions are made as to means whereby this difficulty can be overcome. Legalized quarantine of infected persons is recommended, and the best and most easily available methods for treating infected persons are outlined.

There is one preventive measure, however, of which no mention is made in the memorandum, and that is direct prophylaxis. In Egypt, where venereal diseases of the worst type are rife, and where for longer than three years thousands of British troops have been stationed, direct prophylactic methods have met with great success. During the first few months of the war no prophylactic measures were employed among the soldiers in Egypt, and the result was that many thousands of the best British troops were infected and rendered inefficient temporarily or permanently. Since the introduction there of Metchnikoff's mode of prophylaxis by an ointment containing 25 to 30 per cent. of calomel, applied as soon as possible after intercourse, and before, if desired, the incidence of venereal disease has shrunk to almost negligible proportions. It is stated on good authority that similar results have followed the employment of such measures in European cities, and especially in Italian cities. Direct prophylaxis has been practised in the U. S. Army for several years, but opinions appear to be divided as to its efficacy. Some hold that the method is of little or no avail, while others state that when the ointment has been employed in proper strength and sufficiently early, the outcome has been most satisfactory. Accounts from Europe and Canada are extremely laudatory regarding direct prophylaxis, and some of its advocates go so far as to say that venereal diseases are the easiest to stamp out, and that this object can be effected in a comparatively short space of time. In short, testimony from Europe and Canada seems to be fairly conclusive as to the efficacy of direct prophylaxis. The stumbling block to its general use in Great Britain is the opposition that has been aroused by those who think its general adoption would remove a check on immorality.

It is certain that means must be taken to control venereal diseases, and the move made by the Public Health Service, the Red Cross, and the Medical Department of the Army, not only affords evidence that the peril is recognized, but is an earnest that efforts will be directed to protect soldiers and civilians from the scourge.

RELATIONS OF TUBERCULOSIS TO SCLEROTIC PROCESSES IN THE LIVER AND KIDNEYS.

THAT the tubercle bacillus is able to produce a series of forms of cirrhosis of the liver has long been known as a result of the labors of the French school of pathology; and Schoenberg has recently declared in the *Correspondenz-Blatt fuer Schweizer Aertze* for December 15, that these finds have been confirmed by the pathologists of his country. Of greater interest at present are the relationships which subsist between tuberculosis and cirrhotic kidney. The writer recalls a case of sudden death from uremia in an advanced consumptive which at the time was almost unique in reference works. Only recently was he informed by an experienced pathologist that advanced cirrhosis of these organs was almost never encountered in autopsies on consumptives. Schoenberg mentions under this head amyloidosis and various degenerative changes, such as have long been known and attributed to the toxic element of the infection. He adds that in almost all kidneys in tuberculous subjects there is to be found a slight increase of interstitial tissue. These lesions may resemble healed infarcts and, when present in a high degree, they constitute a special form of contracted kidney. Schoenberg claims to have been the first to describe a second form of tuberculous contracted kidney. This bears a resemblance to scarlatinal nephritis and, like the latter, ends in destruction of the parenchyma and increase of the connective tissue with subsequent fibrosis. He describes a case of typical interstitial nephritis with uremic symptoms in a woman, the autopsy showing a combination of arteriosclerotic kidney with ordinary sclerosis. But in this case the kidneys were the seat of actual tuberculous lesions which were not present in any other organ of the body. Still other forms of tuberculous cirrhosis exist in the kidney the presence of which can be shown only through demonstration of the bacillus and by inoculation. Schoenberg believes that our knowledge of tuberculous cirrhosis of the liver can be made to apply throughout to the kidney of the tuberculous individual.

MALARIAL AMNESIA.

THIS phenomenon is said to be extremely common where malaria prevails, but it has received very little attention. It may be the sole nervous expression of the disease or be associated with headache, vertigo, tremor, etc. In the polyneuritic psychosis of malaria it is one of the most characteristic symptoms. In primary malarial fever it is apt to be lacunar, and at a later period retrograde and anterograde. De Brun considers this subject in *La Presse Médicale* for November 1. The severe initial crisis, with its high temperature, is often completely forgotten. This would not seem strange in cases with

delirium, but such cases are not included under paludic amnesia. The patients may or may not be mentally confused during the access, but amnesia persists in both classes. On the other hand, subjects who can vividly remember the first access may later develop memory troubles. When amnesia is present the memory may at once clear up or continue to give trouble. The retrograde type may be expressed by complete loss of memory for names and rank of comrades and officers. This forgetfulness is not due to military life, for it is seen in the same degree among civilians. Anterograde amnesia seems to have a different mechanism, and to depend largely on weakened attention as a result of the malarial infection.

News of the Week.

State Department of Health Urges Vaccination Against Smallpox.—A recent bulletin issued by the State Department of Health shows that since January 1, 1918, there have been reported to the State Department of Health 375 cases of smallpox, 100 of which occurred in one city. A recent outbreak of smallpox in one of the Indian reservations cost the taxpayers of the State \$8,000. In a number of instances the disease has been found among traveling salesmen and in hotels, barber shops, and stores. Dr. Biggs urges upon all unvaccinated persons, not only for their own sake but as an obligation on good citizenship, to be vaccinated at once, and on parents and guardians to see that children are vaccinated. It is pointed out that the importance of the appearance of smallpox at this time is greatly increased by the military situation and the vital necessity of protecting our camps from the introduction of contagious disease from the civil population.

The Marriage Law in New York State.—Health commissioner, Dr. Hermann M. Biggs, believing that it is important to disseminate through the State exact knowledge of what is required by the present marriage law, has sent a placard to all town and county clerks which he requests them to post in their offices. The letter states that Dr. Biggs believes the amendment to the marriage law, enacted at the last Legislature, should in time become an important factor in educating the people throughout the State to the importance of clean marriages, and of controlling venereal diseases. The placard calls attention to the fact that no marriage license will be issued until both parties swear to the following statement: "I have not to my knowledge been infected with any venereal disease, or if I have been so infected within five years I have had a laboratory test made within that period which shows that I am now free from infection from any such disease."

A Case of Anthrax at Bellevue.—A man from New Brighton, Staten Island, was taken to Bellevue Hospital, on January 28, suffering from anthrax. The infection is believed to have taken place through a scratch in the neck which occurred some three weeks ago and which apparently healed. The man is supposed to have been infected by handling hides. This is the fourth fatal case of anthrax occurring at Bellevue during the past thirteen months.

Hebrew Infants' Home Prospers.—The eighteenth annual meeting of the directors of the He-

brew Infants' Home was held on January 27. Addresses were made by Mayor Hylan and the Hon. Bird S. Coler, pledging the support of the city to the work of the institution. The annual report shows that 500 infants and children under five years of age were cared for during the past year and homes found for about one-half that number. Never in the history of the institution have there been so few serious ailments among the children as at the present time.

Colony Planned for Feeble-minded Women.—At a recent meeting of the Women's City Club of New York plans were proposed for the colony care of feeble-minded women. The plan suggested provides for the taking over of the small colony just outside of Westerleigh, Staten Island, by Randall's Island. The fund of \$200 needed to furnish the colony at Randall's Island has been raised by the Women's Club. Under the colony plan high grade mental defectives live at the colony and go out to work under supervision.

Health Department Examination of Employees.—The method adopted by the New York City Health Department of making periodical examinations of its employees has now been in effect since July, 1914, and 70.2 per cent. of the employees have availed themselves of this service. A comparison of the results for the years 1916 and 1917 shows that, in 1916, there were 3,233 employees on duty, while in 1917 there were 3,009. In 1916 the total number of working days was 1,112,842; in 1917, 1,057,292. The total number of days absent on sick leave was 19,879 in 1916 and 20,656 in 1917, or 1.8 per cent. of the time lost by sickness in 1916 and 1.9 in 1917.

Vital Statistics of New York City for 1917.—Statistics prepared by the Bureau of Records show that the death rate for 1917 was 13.78, which is the lowest rate ever recorded in this city. The rate for 1916 was 13.89 and for 1910, 16.00. This lowered death rate has been effected largely through the reduction in the mortality in the early year of life. Another factor in lowering the death rate has been the reduction in the prevalence of certain infectious diseases. This reduction has been most pronounced in the case of typhoid fever, which, despite the large increase in the city's population, has been reduced from 588 deaths in 1910 to 229 in 1917. The respiratory diseases continue to be responsible for a large number of deaths annually, the rate of pneumonia of all forms being 1.93 for 1917, which is exactly the same as in 1913. The death rate from tuberculosis shows an increase over that of last year, the rate being 1.55 in 1917 as against 1.50 in 1916. The common infectious diseases—measles, scarlet fever, whooping cough, and diphtheria—show a considerable decrease as compared with the rates ten to twenty years ago. In contrast to this certain diseases of adult life, as heart disease, Bright's disease, and cancer, fail to show any decrease and the death rate from cancer continues to increase, the rate being 0.77 in 1910 and 0.86 in 1917. There were last summer 539 deaths from heat stroke, the largest number from this cause in New York since 1901. The death rate from automobile accidents shows an increase from 5.64 per 100,000 in 1913 to 9.07 in 1917. The number of suicides in New York decreased from 836 in 1916

to 768 in 1917. The year just past shows an increase in the number of marriages from 9.68 in 1910, 9.78 in 1916, and 10.49 in 1917.

The Brooklyn Surgical Society held its annual open meeting at the building of the Kings County Medical Society on February 7. The program of the evening included an address by Col. Claude Kyd Morgan and a paper and motion picture demonstration of the "Carrel Method of Treatment of Infected Wounds" by Lieut. George Loewy of the French Army Medical Corps.

Epidemics in Petrograd.—Reports that typhus, smallpox, and other diseases are decimating the population of Petrograd have been confirmed. Spotted typhus is said to be raging with unprecedented severity, there being 428 cases in one barrack hospital alone, and from fifteen to twenty new patients are being received daily. Gastric typhus and smallpox are also said to be epidemic. The people have been warned to regard sanitary measures, but there is no longer a sanitary bureau; there is no sanitary commission; no registration of diseases; there are no great specialists, and few doctors.

Epidemic of Intestinal Disturbances in Montclair.—A break in the Little Falls Filter which is supposed to protect the water supply of Montclair, N. J., is believed to be responsible for an epidemic of intestinal disturbance which is prevalent in that city. Some 1,500 residents are on the sick list.

National Child Welfare Campaign.—The Children's Bureau of the United States Department of Labor, Washington, D. C., announces that it will inaugurate, on April 6, one year from the time the United States declared war, a nation-wide campaign, to be continued for one year, to save one hundred thousand of the nation's children. Each State will be assigned a definite quota of the one hundred thousand lives to save. To inaugurate the campaign there will be a nation-wide weighing and measuring of babies and children of pre-school age. The endeavor will be made to show each community what its children need if the rising generation is to be free from the physical defects which the draft has revealed. The methods of work will be those which have already proved efficient in saving children's lives in the United States and other countries. Dr. F. Truby King, who is the active head of the New Zealand Society for the Health of Women and Children, expects to be in the United States in about three weeks, and it is hoped that his presence will give added emphasis to the campaign.

Dr. Fred D. Jones of Springfield, Mass., has been appointed pathologist and bacteriologist to the Noble Hospital of Westfield, Mass.

Dr. Mark J. Schoenberg has been appointed attending surgeon to the Hermann Knapp Memorial Eye Hospital, New York City.

The New York Orthopedic Dispensary has received \$3,000, the proceeds of a benefit entertainment.

Newark Studies Problem of Drug Addicts.—The Citizens' Committee, appointed by the Mayor to investigate the subject of habit-forming drugs in that city and to make recommendations, has submitted a report recommending that a clinic be established in the City Dispensary for the study and

treatment of narcotic addicts. So far as the committee knows no such clinic is in existence anywhere. The tentative plans for making an exhaustive study of the subject have been submitted to the Health Officer with the suggestion that the clinic be opened immediately.

The Ossining Hospital has received an endowment of \$25,000 in Liberty Bonds from William Rockefeller to be known as "The Mr. and Mrs. William Rockefeller Fund."

Germany's Birth and Death Rate.—A dispatch from the *London Times* is authority for the statement that nothing is causing Germany more concern to-day than the decline in her birthrate. The falling off in the birthrate is said to be greatest in the large towns. As an example, in Dresden the excess of births over deaths fell from 6,853 in 1903, to 965 in 1915. Up to October, 1915, the number of births in Dresden was regularly in excess of the number of births, whereas since that time there has been an excess of births in only two months, namely, May and September, 1916. In the last two months of 1915 the deaths exceeded the births by 108. In 1916 there were 6,440 deaths compared to 5,817 births.

Medical Society Elections.—THE UPPER MISSISSIPPI MEDICAL SOCIETY, at its annual meeting at Brainerd, Minn., on January 8, elected the following officers: *President*, Dr. J. B. Holst of Little Falls; *First Vice-President*, Dr. Alexander Watson of Royalton; *Second Vice-President*, Dr. F. H. Allen of Staples; *Third Vice-President*, Dr. John C. Koch of Blackduck; *Secretary-Treasurer*, Dr. J. A. Evert of Brainerd.

THE DEER LODGE MEDICAL ASSOCIATION, which met in Anaconda, Mont., on January 8, elected the following officers: *President*, Dr. T. J. McKenzie; *Vice-President*, Dr. C. C. Albright; *Secretary-Treasurer*, Dr. John Noonan.

THE KENTUCKY MIDLAND MEDICAL SOCIETY, which met in Paris, Ky., on January 11, elected the following officers: *President*, Dr. C. A. Vance of Lexington; *Vice-President*, Dr. J. Toll of Lawrenceburg; *Secretary-Treasurer*, Dr. D. J. Maguire of Lexington.

THE ELKHORN VALLEY MEDICAL ASSOCIATION, at its annual meeting in Fremont, Neb., on January 10, elected the following officers: *President*, Dr. John Reid of Pilger; *Vice-Presidents*, Dr. H. N. Morrow of Fremont, and Dr. H. A. Skelton of Spencer; *Secretary*, Dr. A. P. Overgard of Omaha; *Treasurer*, Dr. S. A. Preston of Fremont.

Obituary Notes.—Dr. HEINRICH STERN died at his home in New York City on January 30, at the age of 50 years. He was born in Germany and came to this country when he was twenty years of age. He was a graduate of the College of Physicians and Surgeons, St. Louis, in 1899, a member of the American Urological and American Public Health Associations, the New York Academy of Medicine, and many other medical organizations. He was one of the organizers, and, at the time of his death, secretary of the American College of Physicians. He was visiting physician to St. Mark's Hospital and the Methodist Episcopal Home, consulting physician to the Seney Hospital at Central Islip, L. I., the United Hospital, Porchester, the Glens Falls Hospital, and the Union General

Hospital of Boston. Dr. Stern was the founder of the *Archives of Internal Medicine* and the author of a number of books.

Dr. FREDERICK A. DAVIS, a retired physician, died at his home in New York City, on January 14, at the age of 80 years.

Dr. CHARLES J. RUMRILL, of Barre, Vt., a graduate of Dartmouth Medical College, in 1900, died on January 7, aged 46 years.

Dr. HARRY A. SHELLHAUSEN, of Washington, D. C., a graduate of the University of Washington Medical School, in 1899, died at the residence of relatives in Brooklyn, on January 17, aged 43 years.

Dr. CHARLES W. BROUGHTON, a graduate of the Northwestern University School of Medicine, in 1901, died at his home in Youngstown, Ohio, on January 5, aged 44 years.

Dr. GLOVER D. MARTIN, for many years a practicing physician of Beaumont, Tex., died at his home in that city, on January 5.

Dr. WILLIAM R. POLK, a graduate of the Medical Department of the University of Pennsylvania, in 1881, died at his home in Minneapolis, on January 4, aged 64 years.

Dr. HENRY P. WOODWARD died at his home in Pembroke, Ga., after a long illness, on January 9, at the age of 84 years.

Dr. THEODORE COOKE, Sr., of Baltimore, died of injuries received in an automobile accident, on January 13, at the age of 80 years. He was graduated from the University of Maryland School of Medicine, in 1859, and was a member of the Medical and Chirurgical Faculty of Maryland.

Dr. CHARLES TAYLOR JEWETT, a graduate of the College of Physicians and Surgeons, New York, in 1868, died at his home in New York City, on January 18, aged 70 years.

Dr. SAMUEL BOYD LITTLE, a graduate of the Southern Medical College, Atlanta, in 1898, died of pneumonia at his home in Colbert, Ga., on January 9, aged 48 years.

Dr. WILLIAM E. HARWOOD of Joliet, Ill., is reported to have died of pneumonia "somewhere in France," about January 7, at the age of 59 years. He was a graduate of Rush Medical College, in 1880. Dr. Harwood was one of the first to respond to the need of surgeons in the war area.

Dr. ALLAN A. WYCHE, a graduate of the Leonard Medical School, in 1897, died at his home in Charlotte, N. C., on January 7.

Correspondence.

THE TREATMENT OF LOBAR PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—At the present time when lobar pneumonia prevails epidemically, claiming many victims daily, the following lines based upon an experience of many years may prove to be of value. There are among physicians a great number of so-called "drug-nihilists," especially in pneumonia, who use only some indifferent medication, leaving the whole therapeutic work to "fresh air." I would not deny or even minimize the great value of fresh air in the treatment of pneumonia; what I want to say is that the drug treatment is also of great, and may be equal, value and should not be neglected. These

lines will, therefore, serve as a warning to many and also as a hint regarding the drug treatment.

The use of expectorants in pneumonia, which is ignored by many physicians, has proven in my experience to be of very great importance. Not long ago a colleague in a conversation asked me whether or not I used expectorants in pneumonia, and when I answered emphatically "Yes" he seemed to be somewhat surprised. But here the physician has to show his skill in selecting the drug. The selection of the expectorant depends wholly upon the pathological conditions at the given moment; it is, therefore, important that the physician should recognize the exact condition of the patient and the stage of the disease. When we consider, for instance, that in the second stage (red hepatization) the affected part of the lung is consolidated, firm, and solid, it is clear that on *inspection* there will be a marked deficiency of respiratory movement, on *percussion* dullness, and on *auscultation* bronchial breathing. In this most important and decisive stage, it is clear that a powerful solvent is imperative. The "mistura solvens" (Ammon. chlor., Succ. liquirit., $\text{â}\text{â}$ 0.3; Aq. dest., ad 15.0 every 2 hours) has rendered me excellent services. Camphor internally, at the same time, gives very good results. I prescribe it in combination with benzoic acid and powdered digitalis, and I am always told that 10 to 15 minutes after the patient took the medicine he expectorated a "lot of big thick pieces" of sputum, after which he felt more comfortable and the breathing was more quiet—a condition not to be underestimated, as it is more liable to prevent "gray hepatization" and the formation of abscesses, and will sooner terminate in "resolution" and absorption. In this stage (resolution and absorption), it is clear an absorbent and an expectorant will be of great value. I give potassium iodide in combination with anisated solution of ammonia, and have always been satisfied with the results. Strychnine should be given through the whole second stage and part of the third stage. Some advise giving creosote as an antiseptic, but I prefer guaiacol carbonate in combination with strychnine. Alcohol is also very useful, especially in those accustomed to its use in excess. In congestion and delirium due to alcoholism or in affection of the upper lobes venesection has proved to me life saving, relieving the right ventricle.

In outlining here clearly the scientific treatment of lobar pneumonia, based wholly on the pathological conditions, which I have been using and with which I have been comparatively successful (I have omitted serum treatment, not having experience of my own), I am sure it will be of help to some practitioners, especially now when the number of cases is increasing daily. H. RABINOWITSCH, M.D.

432 WEST THIRTY-FOURTH STREET, NEW YORK.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

THE Y. M. C. A. IN FRANCE—EXPLOSIVES—PARIS VITAL STATISTICS.

PARIS, January 2, 1918.

THOSE of us who remember the Y. M. C. A. in the United States have to rub our eyes to see whether the organization in France can really be the same

thing. Here it is emancipated, with full scope for enlarging its sphere. It is confronted with problems that arise from day to day, new, perplexing, absorbingly interesting. All obstacles have to be overcome, and right away. The Y. M. C. A. is now as necessary to the camp as the hospital and medical corps. It is part of the institution of the American army. It has its sphere. It has enough to keep it there. Its future is certain. It necessarily puts the organization at home in a sort of state of evolution. When the war is over and the members of the Y. M. C. A. return home they will take back with them their experiences of life, their experience in being at death grapples with the great problems of existence. What will be the effect of this experience when the Y. M. C. A. forces return home? Will it work out a sort of Reformation?

Not only in our big cities is this work apparent, but in the camps also. The same thing goes on in both, though the circumstances and environment are, of course, essentially different. The other day, I was looking about a town somewhere in France to get transportation to a military camp. Espying two strong, energetic-looking young men in khaki driving a big auto truck, I was soon invited to share the journey with them. "But, wait," said one of them, "until we have got our load on." The truck stopped before a store and the young men immediately without further parley commenced loading large cases of some heavy merchandise on the truck. They handled their loads like men accustomed to that sort of thing in their native land, but their faces showed them to be men of superior education and refinement. I believe we took on some forty of these cases, and then one of the young men climbed on top of the pile and the other courteously invited me to sit beside him. Then we bowled along to the camp.

One of these men was Mr. Heber R. Harper, acting divisional secretary of the Y. M. C. A., and the other was the Rev. Walter John Sherman, pastor of the Union Congregational Church, Winthrop, Mass. Mr. Harper is a Ph.D. and professor of New Testament Greek and of Hebrew in the Boston University School of Theology. In constant daily contact with these gentlemen and their colleagues, it was a pleasure to see how thoroughly they identify themselves with their work. Nothing is too hard for them to do. They clean automobiles, run them, build huts, go here, go there, go everywhere, and do good all the time by example, a kind word of encouragement. No humbug, no cant, just American Christian gentlemen, everywhere and all the time. It is this sort of thing that makes the "cafard," so terrible in some military camps, impossible in our American centers. American women are with them, helping, sharing all sorts of ups and downs which might be supposed to throw the feminine world into chaos at home, all done simply, philosophically, and courageously.

And what I saw in the camp referred to goes on unrecorded all over our American camp centers. Mr. Harper told me: "We commenced here in July last, with an enormous tent. We had about 1,000 men there every evening, and we had boxing, wrestling, and musical entertainments; regimental bands played inspiring music. We had lectures, theatrical evenings, and from time to time prominent people

gave us addresses. Once a week we would have an address on moral rather than religious subjects. Our tent was a feature. Men tore up their passes to go to adjoining villages and towns and passed the evening with us. That tent is being boarded up and will make a good winter building for entertainments. It is fitted with a stage and is well lit by electricity. The permanent equipment consists of three huts placed at the extremities of the camp, so that they intercept the men on their way to the adjoining town. Each of these huts consists of double barracks. The two main huts will do the work of our temporary equipment. One barrack in each hut will be used for a canteen, writing-room, and billiard-room at the end, and the other will serve as a concert hall, class-rooms and reading-rooms. We have space for storerooms, kitchens, mess-rooms, lavatories, offices, and sleeping quarters. Each hut has a large open fireplace for logs. There is a third hut in construction in the town itself, and you can see the building going up. When the boys get into town they will see this nice, comfortable, clean hut and go in and find hot drinks and all sorts of games.

What is noticeable is that a great deal of work of construction is done by the members of the Y. M. C. A. itself. These men are not experts, as most of them are college boys, professors in colleges, pastors, and students from all over America. They do not mince matters, however, but set to work in American spirit and get things done. The army officers realize that the men have to do something in their recreation hours, and everywhere throughout the American camps in France the Y. M. C. A. is recognized as a part of the system of the American army organization.

Dr. Villejean, inspector of the Explosives Department of the Seine Prefecture, who was a pupil of the great chemist Berthelot, appears to favor a very plausible theory; namely, that the stupendous forces bottled up, so to speak, in the receptacles made for them by modern hands exercise a mutual attraction, the vehicle of which is the "emanation from the substances employed." In the case of the Halifax disaster, there was another more deadly, more effective, and more dangerous medium, petrol. He says: "I do not believe in spontaneous explosion. During my scientific career I have never met one authenticated case; but I do believe in detonation or explosion brought about by influence."

Asked whether he had any theories regarding the many explosions occurring in munition factories, he said: "I believe the greatest care is taken in the development of these explosives. Every step is tried and tested before another is taken, as well as every precaution that certain ingredients are not brought into close proximity. But what does happen, I fear, is imprudence—a momentary imprudence, if you will, but one which is often attended with disastrous results.

"The destruction of the great German chemical factory at Griesheim could easily have been brought about by the imprudence of a member of the staff in bringing two substances into too close proximity, causing a local explosion which could be sufficiently intense to detonate all the other explosives in the place by 'influence.'

"There is also another hypothesis that is worthy of consideration and study by experts—that is, the

action of 'les ondes électriques,' or emanations from substances employed in the manufacture of explosives. Such action might or might not be the influencing cause of others of a more serious nature. That many of the explosions during the past two or three years were due to malevolence is certain. There have been others, however, in which malevolence had no part, but where imprudence was the contributory cause of detonation by sympathy—'detonation par influence.' To guard against this latest danger too much care cannot be exercised."

Paris vital statistics for the forty-ninth week of the year: 772 deaths (previous week, 640; season's average, 915). Typhoid fever caused 8 deaths, measles 1, whooping-cough 5, diphtheria 5, infantile diarrhea 10. There were 25 sudden deaths and 5 suicides. Marriages numbered 538 and births 592—263 boys, 329 girls.

1. Research Problems in Tuberculosis.—Edward R. Baldwin, director of Trudeau Foundation, gives three main classes of problems that may be taken as applying to tuberculosis as well as to most diseases to a greater or less degree. (1) There are the fundamental causes of disease, their origin and the reasons for their existence. (2) The natural and acquired resistance to disease. (3) The best methods of prevention and treatment. In tuberculosis there is already known the nature and actual infective agent in its causation, but more light is needed on the origin of the germ. There are now recognized three main varieties of the tubercle bacillus—those of the human, bovine, and the fowl. There are evidences of intermediate varieties, and yet the main types do not change into one another. Pains-taking study has been made and is still in progress to recognize the nature of virulence, *i.e.*, the disease producing powers of tubercle bacilli. With this knowledge in our possession one can comprehend the advantage of estimating the seriousness or mildness of any individual case of disease. Also the body has to be adapted in some way to form a culture-ground for the germs. It is thus evident that the old inheritance idea may not be wholly cast out. A more fundamental study of heredity is necessary. This will involve especially a comparison between families who have had the disease with those who escape. There are broad problems of race, soil, climate, geographic position, diet, habits, as well as chemical and, possibly, physiological functions, that are closely connected with the development of this disease. Much importance was attributed to predisposition to tuberculosis in past years; but it is now known that infection is possible to all, and a predisposition is not necessary for it to take place. The result of the infection, however, is probably greatly dependent on still unknown factors of chemical or vital nature. It is now a pretty well established fact that a small percentage (from 6 to 12 per cent.) of tuberculous children become infected with bovine bacilli. The frequency of adult infection is an important question, as it appears to be relatively infrequent. In most cases of pulmonary tuberculosis it is possible to say that the infection might have occurred in early childhood and youth. On the other hand, such early infections frequently never spread, leaving a suspicion of a second infection as the cause of the ultimate disease. As to the manner of obtaining the infection, inhalation of the either dry bacilli in dust or moist bacilli in the form of spray causes most of the infection. Industrial

centers are notoriously the places where tuberculosis thrives. Hence the improvement of working conditions, such as has already been started in some sections, is necessary in order to cope with this disease. One reason that no harm follows infection in so many people is that they escape other dangers that tend to awaken or spread an innocent tuberculosis. Severe influenza, measles, whooping cough, and other acute respiratory diseases have much to do with breaking down the normal resistance. The treatment of tuberculosis in the individual patient should resemble the methods of Nature, nor should one interfere too much with Nature by administering depressing drugs. *Rest* is the first requisite in active or progressive disease. It is well supported by experience and experiment. *Food* in abundance and variety—there is no better medicine. *Fresh air and light* also in abundance. *Regulated exercise* during convalescence or quiescence of the disease. *Medication* for symptoms as they arise, and chiefly when complications cause severe pain or distress. *Lastly, a wise physician*, gifted with common sense and understanding. These are the great principles of treatment, and, doubtless, they will be required as adjuncts of the greatest specific that the world may yet find.

4. **Otosclerosis.**—M. W. Fredrick points out the inability of cure for these patients, and considers that the causal connection between otosclerosis and syphilis seems very alluring in spite of the absence of other stigmata of hereditary syphilis, the negative findings of the Wassermann test, and the fact that anti-syphilitic medication is absolutely valueless. The bone changes are identical with the bone changes in syphilis. He further considers that the most important thing in otosclerosis to-day is the prophylactic side, and in this way we may be of real benefit to the otosclerotic. Whether this can be extended to treating all the members of the family in which otosclerosis has shown itself from infancy with antiluetic or phosphorus is a mooted question, but those who are under suspicion of having inherited the otosclerosis strain should be under constant care. As children their mothers should be warned against unduly exposing their bodies, as, for instance, by having them go about in bare legs and without hats in all kinds of weather. By hardening their bodies they at the same time are hardening their ears. Chilling of the surface whether through swimming, shower baths, wetting the head, or any other cause should be avoided, as should all so-called colds. Automobile riding is bad; also exposure to wind and weather, as shown by the large number of severe cases of otosclerosis among country people. The idea of heredity is well spread among the laity, and the authors state that it occurs in from 9 to 82 per cent. It should be borne in mind that the heredity need not be a direct one, but is more often a collateral one, and that a good deal of seeking is sometimes called for to discover the otosclerotic ancestor, due to the well-known indifference of most people in these matters. Hitherto it has been thought that these cases were due to local causes in the nasopharynx, and overzealousness in removing any and everything which might lead to local inflammations and their sequelæ was the result. School inspection might help, if one could tell the instructors how to recognize the early stages of otosclerosis, but this is, so far, an unknown art. The otosclerotic woman, like the tuberculous woman, should avoid pregnancy; while pregnant she, like the tuberculous woman, seems to improve very much generally, but after parturition her hearing grows decidedly worse. The outlook for the otosclerotic girl is anything but cheerful. To translate the epigram of a French author: for the girl, no marriage; for the wife, no child; for the mother, no nursing.

While the mother may be willing to sacrifice her hearing for the joys of motherhood, she should remember the hereditary taint she is conveying to her child. There is one feature of otosclerosis which should make us strive to find some relief for the sufferers from this trouble, and that is that, whereas the people who are deaf from old adhesive processes of the middle ear or degenerative nerve changes are, as a rule, old people whose life has been lived, and whose position in life has been secured; who have passed through the pleasures and disappointments of early and middle life, and can afford, as the saying is, to take a back seat, the otosclerotics belong to the younger class, who are just starting out to take their places in the world's work and pleasures. Small wonder that so many of them become victims to the numerous neuroses and insomnia, when it is realized how hard it is for them to make progress in the face of the prejudice against the deaf, how many pleasures they are being deprived of, and how hard it is to conceal their infirmity.

2. **A Report of Vaccine Therapy in a Series of Prostatic Cases.**—H. C. Bumpus reports the results obtained from the use of vaccine therapy in the treatment of prostatic cases at the Mayo Clinic from May, 1917. In undertaking this study he says that it seemed advisable to give all the patients the vaccine for five months and then to compare the results with those obtained in the previous five months without the vaccine. Further to make the two series as synchronous as possible, all cases in which the two-stage operation was done (that is, suprapubic drainage followed by prostatectomy) have been considered separately. The vaccine was administered twice a week in doses beginning with 50 million, increasing by multiples of 50 to a maximum of 500 million, and continuing throughout convalescence. Following the technique of Cabot and Crabtree, mixed colon vaccine was used, prepared from various strains of colon bacillus isolated from different urines and prepared fresh once a week. The administration was subcutaneous and, with two exceptions, no untoward symptoms resulted. The majority of patients complained of malaise with slight nausea and a little rise of temperature during the first few inoculations. The reactions resembled those usually associated with the administration of typhoid vaccine. To determine results, a comparison of the patients treated with vaccine with those not receiving vaccine must be made relative to the incidence of complication manifestly due to infection, namely, pyelonephritis, epididymitis, phlebitis, cystitis and wound infection. The last two conditions it seems best to disregard, as both are almost universally present to a mild degree in such cases, and their relative severity is difficult to use as a matter of careful comparison. Pyelonephritis is naturally the best criterion. The characteristic symptoms of malaise, accompanied for several days by gradually increasing fever with chills and sweats and a subsequent decline, make it typical; and to one who has been long associated with patients who are having residual urine repeatedly removed, the so-called "reaction" can never be forgotten. Cabot and Crabtree have reported a series of cases in which the colon bacillus was obtained during such reactions, especially during the chills, in pure culture from the blood stream. Bumpus and his coworkers in repeating this experiment on six cases obtained only sterile blood cultures. He states that in the series in which vaccines were given there was 5 per cent. less of cases of pyelonephritis than the controls, and 1 per cent. more than all cases. However, it must not be concluded that the vaccine has produced this decrease;

for if the action of the vaccine were specific, a greater reduction than 5 per cent. should have occurred, and the incidence, as compared with all patients operated on, should have been less—not greater. This conclusion is further supported by the 10 per cent. increase in the cases of epididymitis among patients that were treated compared with the controls. A survey of the length of time the treatment was given is of interest in demonstrating that, although the convalescence of the patients not receiving vaccine is longer by five days, their entire time under treatment is shorter by ten days, showing that the greater the length of preoperative preparation the shorter the convalescence. This fact is further emphasized in the two-stage series, when a preparation of several hundred days is given to patients who are the poorest of surgical risks, and leads to a convalescence much shorter than the average. In the two-stage series no attempt was made to chart the incidence of infection, because much of the patients' preoperative time was spent at their homes, where accurate observation was, of course, impossible. Bumpus works out the following conclusions from this experimental work: (1) Immunity to pyelonephritis by means of mixed colon bacillus vaccine cannot be produced. (2) The administration of mixed colon vaccine does not markedly reduce the incidence of genitourinary infection, if it affects it at all. (3) Preoperative attacks of pyelonephritis are the natural means of producing an immunity to renal infection, and their occurrence makes operative risks less. (4) The length of convalescence is usually in inverse proportion to the length of preoperative treatment.

3. An Analysis of Recent Tetanus Statistics.—F. Golla, member of the War Office Committee for the Study of Tetanus, has obtained his conclusions from the tetanus statistics of the period from 1916 and early part of 1917. There were 640 cases occurring in British hospitals in England and France under consideration. The total mortality is 50.8 per cent., and compared with the average mortality of the wars of pre-serum days the results are extremely encouraging. This diminution is due beyond question to the prophylaxis administered, and a small part may possibly be due to better methods in dealing with wounds and the consequent improvement in the general condition of the patient. Golla considers further that it is a matter of much difficulty in the absence of controls to ascertain whether in addition to these agencies the specific treatment with serum plays any part in the reduction of tetanus mortality. He makes a comparison of the types of tetanus of pre-serum days and the types found in the present war. The types of tetanus found at the time of the War of Secession were based on the rapidity and completeness with which trismus developed. Rose distinguishes "vehementes," in which the jaws cannot be separated and the complete development of symptoms takes place within 24 hours; "complete lenti," in which there is complete closure of the jaws and the symptoms take more than 24 hours to reach their maximum; "incomplete lenti," cases in which the jaws can be opened a varying degree either by the patient or the observer and the symptoms develop slowly. A certain number of cases of what was called localized tetanus are recorded in the reports of the War of Secession, but the term was used to designate not tetanus localized to the segmental wound area, but tetanus confined to trismus without tendency to spread. In investigation of tetanus of the present day the cases may be divided into three types—those with initial trismus corresponding to the tetanus of pre-serum days, though modified by prophylaxis, and two new types, those with delayed trismus and those with local tetanus. These two latter types, certainly those of local trismus, constitute a new disease and must be

considered separately from cases of initial trismus if any conclusions as to the value of serum treatment by comparison with older statistics are to be reached. In 1870 only 5.7 per cent. of the cases appeared after 21 days, while there are now 30.4 per cent. with an incubation period of more than three weeks. During the first three weeks a lengthening of the average incubation period is also present, though less striking. The most probable explanation of this lengthening of the incubation period is that it is due to prophylactic treatment, and the statistics bear this out on the whole. A comparison of the relation between mortality and incubation in the 1870 campaign and the present one shows that there has been a slight decrease in mortality in the present war and that it is probably due to the prolonged incubation period. If, however, the first three week periods are compared it will be found that during the first two weeks the mortality in the 1916 cases is slightly below that of 1870—i.e., 75.5 per cent. and 70 per cent., as against 96.5 per cent. and 85.5 per cent.—whereas in the third week the 1916 mortality is slightly above that of 1870. This is precisely what could be expected on the hypothesis that the slight initial diminution of mortality is due to the improved methods of rendering first aid to the wounded and abstention from drastic operations. After the first two weeks when the cases of exhaustion and post-operative shock become fewer, the mortality from both statistics becomes practically the same in the third week. Golla considers that it must be conceded that if the slight initial decrease of mortality is all that can be claimed for serum treatment the result is not very encouraging. The statistics from nonprotected cases, though too small to be decisive, also strongly support the view that apart from prophylaxis serum treatment has no influence on mortality. The cases of late trismus show less favorable influences to serum treatment than that of the initial trismus group. Local trismus appears to have no mortality as far as statistics have shown. With reference to the curative action of serum Golla says that there appears no evidence of any appreciable diminution of the mortality of tetanus to be derived from an analysis of the statistics of incidence and mortality when allowance is made for the modification of the disease due to prophylaxis. Another infallible sign of a curative action of serum should be furnished by an examination of the time after the onset of symptoms at which treatment was begun in fatal and cured cases. His statistics show that the periods before beginning of treatment varied from three minutes to three days, and no relation between their duration and the result of the disease could be established. Again no definite results have been established between the amount of serum administered and the result of the case. The statistics were also worthless for any attempt to discover the influence of different methods of administration.

4. Treatment of Thrombosis.—H. Fairley Marris reports on his successful employment of the intravenous injection of sodium in venous thrombosis such as occurs in the typhoid group of fevers. During the past two years seventeen cases of venous thrombosis have been under his care, the majority having arisen during the course of an infection bacteriologically proven to be by a member of the enteric group, the remainder occurring during the course of other fevers of obscure origin. This complication has long been recognized as prolonging convalescence and leading to permanent mischief, such as troublesome swollen limb or the formation of intractable varix. The signs and symptoms as seen in this series were described: rigors in four of the cases. Fever was always present; pain invariably so, on two occasions being so severe that the

question of intestinal perforation arose. Swelling of the limb was always present, usually appearing on the third day from onset of the other symptoms. In most of the cases the thrombus could be felt. Among the enteric cases the distribution was as follows: Left femoral 9, right femoral 1, right and left femorals 1, left iliac 2, right and left iliacs 1. The remaining three cases occurring during the course of other fevers were: Left femoral 2, right and left popliteals 1. The earlier cases were treated on the usual lines—namely, locally with anodyne liniments, and internally by the liberal administration of citric acid and a milk-free diet. The following is the first case treated by the intravenous injection of sodium citrate: A soldier, aged 19, admitted to hospital on the twenty-third day of his illness, which was subsequently shown to be typhoid fever. The temperature was 101° F., and the pulse 106 per minute. By the thirty-second day the temperature had regained the normal by lysis; the pulse rate, however, was still about 100 per minute. On the thirty-fourth day the temperature rose to 100° F., and the patient complained of considerable pain in the lower part of the left abdomen. A thrombus was suspected, but nothing could be felt, and measurements round the two lower limbs at the calves gave the same result—namely, $10\frac{1}{2}$ in. By the thirty-fifth day the left leg was swollen, and on the thirty-seventh day edema was observed in the right ankle. The swelling in both legs increased rapidly, and by the thirty-ninth day the man was in such agony and the abdomen so rigid that the possibility of an intestinal perforation was considered. By the fortieth day the thighs resembled bolsters, and the superficial veins on the lower part of the abdomen became so conspicuous that the inferior vena cava appeared to be involved. A 0.5 per cent. solution of sodium citrate in normal saline was given. Half a pint of this solution warmed and sterilized was slowly run into the median basilic vein of the left arm. Twelve hours later the pain had almost gone. The following day a second injection of 8 oz. was given, and by the next morning the temperature had fallen, the patient was free from pain, and the abdomen was quite soft. A speedy recovery took place. Imperial drink was given before the first injection; thereafter this was suspended. This patient returned to duty 104 days from the onset of his illness—that is, 74 days from the beginning of the thrombosis. In the earlier cases the injections were followed by rigors occasionally, which occurred as early as half an hour and as late as three hours afterward; they were never severe, and were quickly relieved by half an ounce of brandy and hot bottles. With more careful preparation of the citrate solution, using recently distilled water and efficient sterilization, the rigors have not been observed. Rigors are not infrequently observed after intravenous injections of other substances, and this is not an important point. On two occasions an attempt was made to compare the coagulation time of the blood before and after the injections, and in one case the coagulation time of the blood had been changed from two to six minutes. There is a report of seventeen cases treated by this method, and Marris is so satisfied with the results that he has decided to treat all future cases of this type under his care by the oral and intravenous methods alternately.

7. Acidosis as a Possible Cause of Certain Symptoms

in Diphtheria.—B. A. Peters reports his treatment of this condition in the latter part of an attack of diphtheria. If severe cases of diphtheria do not receive antitoxin before the third or fourth day of disease death may occur on the fifth to seventh day from an overwhelming toxemia with signs of heart failure. In a large number of late cases temporary improvement follows rapidly on administration of serum, the throat cleans, the patient is able to take a fair amount of food, and appears to be convalescent. About the tenth to twelfth day the complexion assumes a slightly dusky pallor, food is refused, and vomiting occurs. The vomit at first consists of food, but later becomes like coffee grounds. The patient vomits five or six times a day whether food or drink is given by the mouth or not. The heart's action becomes weaker and the pulse more feeble by slow degrees, until by the third day of vomiting the pulse is imperceptible at the wrist, the extremities become pale and cold, the urine is greatly diminished in quantity, the face assumes an earthy pallor, the liver may be enlarged, sometimes severe epigastric pain is present, occasionally, in older patients, a fear of impending death is present; the consciousness is maintained to the end, which is preceded by a short convulsion. In nine years' experience in a large fever hospital he has seen but one case recover in which this condition was established, and that one was treated according to the treatment to be described. Every severe case coming under treatment late during the past eleven months has been treated at once with 10 to 15 grams of sodium bicarbonate a day for several days in divided doses by the mouth, in addition to full doses of antitoxin. The number of cases admitted was 290; 52 were severe late cases (third day or after), and of these 11 died from all causes, including 5 within 48 hours of admission, and 3 from bronchopneumonia following laryngeal diphtheria; this leaves only 3 deaths from heart failure. Not one of the whole 290 cases had any vomiting, and many unexpected complete recoveries have taken place. The mixture given is: Sodium bicarbonate 2 grams, potassium bicarbonate 0.3 gram, magnesium carbonate 0.5 gram, and water up to 30 c.cm. To be given every four hours. It appears to alter the toxic pallor to a more healthy tint, and increases the urinary secretion and diminishes the albuminuria.

Berliner klinische Wochenschrift.

November 12, 1917.

The Ultimate Result of a Restoration of the Ulna Nerve by Edinger's Method (Agar Tubes). with an Anatomical Examination.—O. Müller and W. Berblinger describe this procedure which, in the case reported, consisted in interposing a piece of a calf's artery filled with agar between the divided ends of the ulna nerve. The result was not favorable, as has been the case in all similar experiments resorted to during the war. The writers describe the results of their findings made nine months after the operation. Both ends of the arterial tube were invaded by the nerve endings but there was no evidence of regeneration. The process resulted simply in the formation of a double neuroma.

The Pathology and Treatment of Five-Day Fever.—C. Kayser considers that this affection is a modified form of malaria which is transmitted by lice and not by the anopheles. It is most susceptible to treatment with quinine.

Münchener medizinische Wochenschrift.

November 13, 1917.

Menstrual Epistaxis and Its Treatment by Organotherapy (Continued from the issue of Nov. 6).—Bab describes the clinical characters accompanying this process, namely, sexual infantilism, anomalies of the pilous system, diminished fertility, uterine displacements and frequent tuberculosis. On the other hand, nasal affections are relatively uncommon. Finally, the writer insists on the hysterical states present as well as dysmenorrhea, and endeavors to explain them by an intoxication due to the retained menstrual flux. Considering the treatment of menstrual epistaxis, Bab proposes in the first place to overcome the amenorrhea, and this is accomplished by the exhibition of an opo-

therapeutic medication, namely, ovarine, thyroidine, etc., or by the administration of hypereminating and aphrodisiac agents. All styptic agents, even in local application, are contraindicated; the medication of choice should be physiological; that is to say, the secretions of the corpus luteum. Bab employs hypodermic injections of this substance and this treatment has generally been found sufficient for controlling even the most severe types of menstrual epistaxis.

Treatment of Gonorrhea.—A. Menzer considers that the end to be obtained in the treatment of gonorrhea is not the disappearance of the symptoms but the disappearance of the gonococcus. The ordinary treatment (silver salts, etc.) effects only the disappearance of the symptoms and offers the great danger of exposing the patient to recurrences of the infection and of communicating the disease to others. It is preferable, according to Menzer, to provoke the gonorrheal discharge by baths and hot injections, diathermy and anti-gonococcic vaccines until sterilization of the vaginal or urethral discharge has been attained. All treatment directed against the discharge itself offers the danger of favoring the retention of the gonococcus.

Treatment of Gonorrhea.—J. Lewinski admits that in principle the ideas of Gauss and Menzer are correct. But in practice they are quite unrealizable because the patients leave the hospital just as soon as the symptoms have subsided. On the other hand, a prolonged treatment of gonorrhea keeps patients from coming to hospitals for care and instead they apply to physicians who treat them with all possible rapidity.

Deutsche medizinische Wochenschrift.

November 17, 1917.

The Comparative Value of Radiotherapy and the Operative Treatment of Uterine Myomata.—W. Nagel is decidedly opposed to the modern tendency, represented (in Germany) by Bumm and Doederlein, which regards the operative treatment of uterine myomata as an anachronism and in its place treats all cases by radiotherapy. A tendency quite the same as this in 1890 resulted in the general application of Apostoli's galvanocautic procedure, now fallen into complete oblivion. Nagel reports a series of 160 cases of uterine myomata operated on by the vaginal route with a mortality of 0. In each case he was able to leave one or both ovaries, therefore assuring the continuation of their normal endocrine functions. This is unquestionably of great importance, particularly in young women, and is a favorable point for hysterectomy. After giving his technique, which in no way differs from that resorted to in the last 25 years, likewise the operative results observed by him, the writer concludes that hysterectomy is by all means superior to the blind and destructive procedures of the radiotherapeutists.

Researches on the Agglutinins in Syphilitic Subjects.—A. Kissmeyer explains the negative results obtained by certain writers on this subject by the use of the microscopic method. The writer makes suspensions of washed, dead spirochetes in salt solution; agglutination takes place at 1/200 to 1/500 and is made evident by a flocculation quite analogous to that of the typhoid bacillus. The results arrived at are summed up by the writer in the following table:

	Aggl.+ Wasser.	Aggl.+ Wasser.	Aggl.— Wasser.	Aggl.— Wasser.
Indurated chancre...	5	3	3	7
Secondary syphilis...	19	1	18	5
Tertiary syphilis...	2	2	4	1
Latent syphilis...	10	7	10	17
Congenital syphilis...	8	0	2	2
Controls	0	*3	0	108

*To these cases, two cases of scarlet fever agglutinating at 1/100 should be added.

Wiener medizinische Wochenschrift.

November 17, 1917.

Medullary Commotion (Continued from the issue of Nov. 10).—J. Bauer concludes that there is a possibility of purely inhibitory functional disturbances taking place, these being quite independent of any psychogenous mechanism. The anatomical proof of this fact being of a negative kind is impossible to realize. There

is good reason to extend this notion to other organs besides the cord and brain, such as the heart, kidneys, liver, stomach, bone marrow, etc., in order to explain the commotional effects of projectiles which have ricocheted.

The Indications of Removal of the Tonsils Derived from the Nervous System in Children.—J. Zappert terminates this paper referred to in the previous number of this journal by the following conclusions: The only positive indication is nasal aprosexia, which is itself uncommon and which is not to be mistaken for neurasthenic manifestations or with a low intellectual development resulting from partial deafness or persistent frontal headache. The other nervous affections, such as nocturnal fright or enuresis, vomiting, asthma, epilepsy, tardy intellectual development, laryngeal spasm, chorea and stuttering are under no circumstances to be treated by removal of the tonsils. Finally, the writer considers the relations existing between the pharyngeal tonsil and the hypophysis as purely hypothetical.

Percussion of the Pulmonary Apices.—N. von Jagić describes his personal technique in determining the upper limits of both lungs and offers clinical deductions derived from the difference in the level of the lungs. The procedure consists in tracing a line on each side, starting at a point situated three fingers' breadth from the middle line between the first and second dorsal apophyses and carried to a median point corresponding to the limit of the hair. Light percussion made over these lines gives the relative level of both apices.

Annales de Dermatologie et de Syphiligraphie.

July, 1917.

Black Tongue and Keratochromoglossitis.—Lebar has made numerous histological studies of this affection with a special technique. It is an easy matter to snip off the papillary filaments and tease them out in water, clear them with immersion in potassium hydrate, etc. Viewed at low power they present no black granulations of pigment such as one would expect to see. In fact the epithelium, hypertrophied and keratinized, does not differ essentially from that of the ordinary sabunal tongue, the habitually loaded or coated tongue. Blegvad, a Swedish investigator, arrived at the same conclusion. Under the microscope the only distinguishing mark is the greater length of the papillæ in black tongue, while the keratinization which is so well developed in the latter does not at first sight account for the black color. The use of solvents of all kinds fail to extract any coloring matter, and the blackness cannot be due to blood pigment, iron or other familiar substance. The author studied especially a patch of black tongue on a pneumonia patient, the death of whom allowed him to obtain an autopsy specimen. The histological study was made by Professor Darier. A second specimen from a dead tuberculous patient was studied under a different technic. Inoculation tests remained negative throughout and generally speaking the parasitic theory, like the pigmentation theory, is without support. The affection consists of two essential features, viz.: Elongation of the filiform papillæ with abnormal coloration of their extremities. Prolonged study appears to show that the latter is not histologically essential or in other words black is only the extreme shade, other papillæ showing all nuances of color from black to brown, coffee and milk, pale, etc., as in ordinary hairs the shade of color is not apparent under the microscope. The changes in the mucosa indicate the presence of a glossitis and this with the tendency to form keratin causes the author to coin the term keratochromoglossitis of which black tongue and habitually coated tongue form two clinical varieties. Among the causes of this condition are local processes in the mouth pharynx and nasopharynx, gastric and pulmonary affections, etc. Irritating chemicals used as buccal antiseptics, such as menthol and potassium chloride are also able to determine these conditions. Smoking can hardly be regarded as an important factor, for out of Blegvad's 73 patients only 16 were smokers, and the author found but 5 smokers among 19 patients. In the individual case of black tongue there may have been staining of some sort involved but any attempt to generalize from these isolated cases must be given up. Keratin has a

faint yellow hue, even under the microscope, and since black tongue doubtless represents the extreme phase of keratinization this coloration must be due to certain optical properties belonging to this substance.

Alopecia in Hereditary Syphilis.—Sabouraud has recently written papers on the syphilitic nature of certain alopecias and on a new dental dystrophy seen, like the preceding, in hereditary cases. He has been criticized because of neglect to take a seroreaction, and for other reasons—the dentists, for example, state that his dental dystrophy is only "Carabelli's tubercle," which is not a specific. Sabouraud has replied that to be a stigma of syphilis the tubercle must be present in a certain degree. In the present article he takes these points up in case histories as follows: (1) A youth of 16 years began to lose his hair without cause. In two and one-half months he had become totally bald, including his eyebrows. The lashes were retained. There were no signs of a beard beyond the down of adolescence. One year later his hair had grown in on the scalp. The usual treatment was given without the patient's knowledge of its nature, and improvement resulted in certain respects, but the author is somewhat vague on the point. He merely states that the "hair on the body" slowly reappeared, although the loss of this was not mentioned among the symptoms. No seroreaction was obtained. The family history was tuberculous rather than syphilitic. One Carabelli's tubercle was well developed. (2) Alopecia areata in a man whose parents were syphilitic. Syphilophobia; a seroreaction was positive. Some dental dystrophy, but no Carabelli's tubercle. (3) Male, 22. First seen when 9 years of age, for alopecia areata. In the interim he had been totally bald, and while most of his hair had slowly grown in, the disease was still active. Wassermann positive. All four molars (two upper posterior on each side) showed the Carabelli tubercle. Of thirteen similar cases a few more may be selected. (7) An overgrown girl of 16½ years, very masculine, mother living, and a woman of noted beauty, showed a small spot of alopecia on one temple. Her mere appearance was suggestive of inherited syphilis. The teeth showed remarkable multiple dystrophies. No Carabelli. Wassermann not taken. (10) A woman of 30, with a relapse of alopecia areata. Father died of aneurism of the aorta. Multiple dental dystrophies. (14) Man of 44. Severe alopecia areata for two years, involving eyebrows, eyelashes, and beard. One very large Carabelli tubercle. Of thirteen children in family but four grew up. Sabouraud claims that alopecia areata must be ranked among the stigmatic diseases of hereditary syphilis.

Acute Hepatic Congestion in the Nursling.—Raimondi describes this condition as extremely common in nurslings. In some cases it appears to be due to prolonged overfeeding, in others to some congenital insufficiency of the organ. In the latter type there is fat intolerance, and in general the infant cannot eat for its age. The condition, common in the first few years of life, is by no means rare in older children. When due to overeating, it is noticeable after trips to the seashore, mountains, etc., as a result of increased appetite. Upon its return to the city the digestion is no longer able to support the appetite. As a rule the stomach is not upset. Diarrhea in particular is absent. The stools show an absence of bile, being pale and fetid. The urine is dark and the only change which is more or less constant is slight glycosuria. The liver is always enlarged and tender, and there is always some rise in temperature, often marked. The condition is described in great detail, but without reference to any constitutional peculiarities. There are nearly enough symptoms present to place these cases under the exudative diathesis of Czerny as far as certain organs are concerned. There is, however, no reference to cutaneous or respiratory phenomena.

Correspondenz-Blatt für Schweizer Aerzte.

December 1, 1917.

Allergy in Cutaneous Diseases.—Lutz refers to the introduction of the term allergy into clinical medicine

in 1906 by von Pirquet to indicate an altered capacity for reaction toward a given irritant. As allergy is preeminently a cutaneous phenomenon it should play a rôle in cutaneous medicine, and, as a matter of fact, is well demonstrated in the ringworm group of dermatoses. This is readily shown in animal experiment. If a pure culture of fungi is rubbed into the smoothly shaven skin of a guinea pig a lesion is visible on the fourth day, reaching its acme on the twelfth day. An area of skin is inflamed and surmounted by a scab which, when removed, exposes an ulcer. After the twelfth day rapid involution occurs, the hair reappears and by the end of the sixth week there is no trace of the lesion. If now the same culture is rubbed into a new shaved area a reaction is seen to occur in twenty-four to forty-eight hours; but, despite this brevity of the incubation period, the inflammation is much less pronounced and quite atypical. It may be decidedly abortive, lasting but three days, and at most does not exceed two weeks. A crusted ulcer never forms—only scaling or pustule formation. The allergy consists of a great diminution in the severity of the reaction, and must not be confounded with anaphylaxis. In allergy the toxins produced by the fungi are absorbed and engender antibodies which bring the inflammatory process to a sharp arrest. After the second inoculation the antibodies which still circulate in the blood inhibit the development of the fungi, and generally speaking, the phenomenon of allergy is a simple one. In the clinic the phenomenon of allergy is not markedly evident in the trichophyton group, otherwise an affection like tinea sycosis might be self-limited, but it is otherwise with so-called tuberculides which occur in great variety, although having common traits. While these dermatoses are benign, and cannot be brought into direct relationship either with tubercle bacilli or toxins, they are in some way related to foci in the body of actual tuberculosis. While direct proof cannot be furnished, animal experiment illuminates the problem. If a culture of tubercle bacilli is rubbed into the shaven skin of a guinea pig a small, firm nodule forms, and ulcerates. It does not heal, and the lymphnodes and entire organism become fatally infected. If now an animal thus inoculated is reinoculated the incubation period, instead of being eight days, as in the first case, is but one day. At first intense, the inflammation soon aborts, and the necrotic hemorrhagic center cicatrizes. In other words, the antibodies in the blood, although powerless to defend the organism at large, are able to inhibit the action of the newly inoculated bacilli, as in the trichophyton case. We must infer that the same analogy holds good for tuberculides in the human clinic, i.e. these are made possible because of antibodies generated as the result of a focus of true tuberculosis in the body. The human subject, by reason of the presence of these same antibodies, has not succumbed to the disease like the much more susceptible guinea pig. Should the protection fall short of a certain degree we see develop not a lichen scrofulosus, or other tuberculide, but actual cutaneous tuberculosis—some form of lupus vulgaris. Between the true and allergic forms we may see transitions. In so-called serum allergy, which corresponds to anaphylaxis, we see a behavior quite analogous to so-called idiosyncrasy (toward shell fish, in particular), due to the presence in the blood of foreign protein. Drug idiosyncrasy and anaphylaxis, on the contrary, are not due to protein antigens, but to chemical reaction bodies of specific character. Second injections of quinine or salvarsan may cause anaphylactic reactions quite analogous to the phenomena of serum anaphylaxis.

Colic Reaction and Pancreatic Organotherapy.—Savini has used pancreatic alone or in combination with bile in mucous colitis and has noted improvement in the painful crises and character of the stools. He was therefore encouraged to use the remedy in all cases of colic reaction and has invariably succeeded in suppressing the latter. He employs pills of dry pancreatic extract and sodium bicarbonate (two parts of the former to one of the latter) with in some cases bile as an excipient.—*Archives des maladies de l'appareil digestif et de la nutrition.*

Book Reviews.

WHITE AND MARTIN'S GENITO-URINARY SURGERY AND VENEREAL DISEASES. By EDWARD MARTIN, A.M., M.D., F.A.C.S.; JOHN RHEA BARTON, Professor of Surgery, University of Pennsylvania; BENJAMIN A. THOMAS, A.M., M.D., F.A.C.S., Professor of Genito-Urinary Surgery in the Polyclinic Hospital and College for Graduates in Medicine; Instructor in Surgery, University of Pennsylvania; and STIRLING W. MOORHEAD, M.D., F.A.C.S., Assistant Surgeon to the Howard Hospital, Philadelphia, Pennsylvania. Illustrated with 422 engravings and 21 colored plates. Tenth edition. Price, \$7.00. Philadelphia and London: J. B. Lippincott Company, 1917.

To the already well filled field of urologic literature comes this tenth edition of a book, which in its twenty years of age has attained popularity through its merit and excellence. In the interval of seven years between the ninth and tenth editions urology has so progressed that the present volume practically is rewritten. The death of Dr. J. William White, to whom this edition is dedicated, removes one of the pillars of strength from the original structure, but Dr. Martin has endeavored to compensate our scientific loss by calling to his aid the three co-authors mentioned on the title page.

Thirty-two chapters covering nearly seven hundred pages are given to the consideration of genitourinary diseases in every phase and from every angle. New chapters and sections are added on such important topics as the examination of the patient, urinary examination and determination of renal function, choice, care, and sterilization of instruments, and extensive amplification of the treatment of acute and chronic gonorrhea. The new text on high-frequency desiccation, the treatment of prostatic hypertrophy, and determination of renal permeability are in harmony with the opinions of other urologic authorities. New sections on renal tumors and parasites, renal tuberculosis, renal operations, nephrolithiasis, and kidney physiology express the latest views and most approved methods concerning this organ.

The last twelve chapters include as extensive consideration of syphilis as is necessary for any but strict syphilographers. An entirely new chapter appears on the laboratory diagnosis of syphilis as well as ample additions in discussion of the arsenicals. The various methods of syphilitic treatment are outlined, but no personal preference is mentioned. Their technique for the inunction method is so different from the standard accepted, that of Aix-la-Chapelle, that their results must be at variance. The authors' gloomy views on the uselessness of intraspinal treatment robs the tabetic or paretic of that faint hope science has offered him.

From first to last each page shows painstaking re-writing, revision, and rearrangement. In the main the views, opinions and teachings are those accepted worldwide, and such discriminating care has been used in giving prominence to the essentials that the work is perfectly balanced. Publications of other writers have been liberally used, but proper credit is given. The authors' literary style is that of teachers, clear and concise. New and excellent illustrations abound and are inserted with good judgment. The colored plates are especially good.

IMPOTENCE AND STERILITY WITH ABERRATIONS OF THE SEXUAL FUNCTION AND SEX-GLAND IMPLANTATION. By G. FRANK LYDSTON, M.D., D.C.L. Price, \$4.00. Chicago: The Riverton Press, 1917.

THE author states in the foreword that the object of this monograph has been to put in more permanent form his theory regarding sexual abnormalities and sex gland implantation. This theory the author terms the sex hormone aberration theory and is, as we see it, based essentially on deficiency in the internal glandular secretion of the testis and ovary. The sex hormone resides in the sperm and germ cells, and depletion in the quantity and quality of this hormone is accountable for both psychic and physical aberrations of sex differentiation. According to this conception sexual perversion and inversion are considered purely biochemic in origin. The first part of the book covers the subjects of hermaphroditism, diseases of the sexual function and

instinct, sexual perversion and inversion, impotence and sterility, masturbation, sexual excess, etc., with their respective treatments. Much of what the author writes is found in some of the old standard books, such as Kraft-Ebing's *Psychopathia Sexualis*. The treatment of impotence, sterility, and sexual dyscrasias generally contains nothing new, with possibly the exception of sex gland implantation, which according to the author is of value in selected cases. He makes a strong plea for this form of therapy, and we cannot but admire his courage in carrying out an implantation experiment on himself. The author claims not only beneficial effects on the sexual function but also secondary improvement in bodily functions as a whole, due to the stimulation of absorbed hormone from the implanted sex gland. This part of the monograph we find most interesting and original in some of its conceptions.

THE MEDICAL CLINICS OF NORTH AMERICA. Volume I, Number II (The Philadelphia Number, July, 1917). Octavo of 269 Pages, 28 Illustrations. Philadelphia and London: W. B. Saunders Company, 1917. Published Bi-monthly. Price per year, \$10. Philadelphia and London: W. B. Saunders Company.

THIS number of "The Medical Clinics" contains much excellent material, set forth in a scholarly and orderly manner. Following is a list of the contributions with their contributors: aortitis, Dr. Thomas McCrae; the classification of chronic nephritis and the relation of infection to kidney disease, Dr. Alfred Stengel; cardiac disease and digitalis, Dr. H. A. Hare; aortic aneurysm: leukemia, Dr. Joseph Sailer; progressive myocarditis; treatment of cardiac decompensation, Dr. David Riesman; the diagnosis of pulmonary tuberculosis by the roentgen ray, Dr. H. K. Pancoast; angina pectoris and allied conditions, Dr. A. A. Stevens; mechanical disorders and irregularities of the cardiac contraction, Dr. R. V. Patterson; gastric infection, Dr. Martin E. Rehfuess; ulcerative endocarditis, secondary to dental caries, treated by autogenous vaccine, Dr. Judson Daland; the diagnostic value of examinations of cerebrospinal fluid, Dr. John A. Kolmer; a case of auricular fibrillation of long duration, Dr. John A. Musser, Jr.; poliomyelitis, Dr. T. H. Weisenburg; essentials and limitations of an average diet, Dr. O. H. Perry Pepper; the causes of reaction under salvarsan, Dr. Jay Frank Schamberg; osteitis deformans, Dr. Elmer H. Funk. The selection of topics as above detailed is sufficiently varied and noteworthy to make the number of more than usual interest.

MEDICAL RESEARCH AND HUMAN WELFARE. A Record of Personal Experiences and Observations during a Professional Life of Fifty-seven Years. By W. W. KEEN, M.D., LL.D. (Brown); Emeritus Professor of Surgery, Jefferson Medical College, Philadelphia. Price, \$1.25. Boston and New York: Houghton Mifflin Company, 1917.

THIS delightful little book embodies the Culver lectures for 1917, given by Dr. Keen at Brown University. A professional life of fifty-seven years affords a rare opportunity at this period in the history of medicine to review an unusual list of discoveries and achievements which have contributed not a little to the welfare of mankind. Dr. Keen describes in a most readable and forceful style the epoch-making work of that giant among scientists—Pasteur, always a predominant figure in writings of this kind. As an instance of the value of medical research along lines of animal experimentation, the author states that during the seven years from 1903, when Metchnikoff succeeded in infecting an ape with syphilis, down to 1910, more was learned as to the cause and cure of this terrible scourge than in *four centuries* of observation. The researches into smallpox, cholera, bubonic plague, yellow fever, etc., the essayist discusses and shows how much the world is indebted to the medical profession for the great decrease in morbidity and mortality of these diseases. We cannot refrain from the thought that such a book as this should be read by our iconoclastic brethren of the Christian Science persuasion, and also by that misguided and fanatical aggregation of sometimes otherwise intelligent people—the antivivisectionists. Dr. Keen has certainly conferred a graceful favor on his profession in putting these excellent lectures into book form.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

*Thirtieth Annual Session, Held at St. Augustine, Fla.,
December 18, 19, and 20, 1917.*

THE PRESIDENT, DR. WILLIAM D. HAGGARD, NASHVILLE,
TENN., IN THE CHAIR.

(Concluded from page 216.)

President's Address: The Medical Profession and the Great War.—Dr. WILLIAM D. HAGGARD of Nashville stated that during the three years of the present war the British with millions of men engaged had lost only 292 men from typhoid fever. Typhus fever had been denied access to the battleground of the far-flung Western Front. We would see to it that it would never gain a foothold in our army camps. The Medical Reserve Corps now numbered nearly 15,000 physicians who had volunteered and been commissioned. The re-education of the crippled, the maimed, the sightless, and the salvaged after the war was a voyage across uncharted seas into another world. No longer would we attempt to save the wounds of heroism with alms, or allow a mutilated patriot to eke out a pitiful existence as best he might; rather would it be our splendid aim so to reeducate that unfortunate as to give him a trade or a profession more lucrative, more independent, and more ennobling than he had had before. In all of the war work the representatives of the healing art had had their share. For the Southern Surgical Association, to its lasting honor, as President he wished to record that out of 200 members, more than 50 of whom were disqualified by age or obvious disability, 70 had given their services to their country.

Some Recent Literature on Shock.—Dr. F. W. PARHAM of New Orleans said that the cardiac factor was not primary in shock, nor was the vasomotor factor. The experiments of W. T. Porter, of Seelig and Lyon, of Seelig and Joseph, of Frank Mann, of Morrison and Hooker, of Yandell Henderson, and many others showed this center to be not paralyzed, but in a state of increased activity, and Pike, Guthrie, and Stewart had shown it more capable than any other center of withstanding the influences of anemia. Low pressure did not prove its exhaustion, for this followed hemorrhage also. Cannon concluded that "we must respect the vasomotor center as an agent whose capacities for continued action are its most outstanding feature." Frank Mann had published some experiments to show that a large amount of blood was retained in the splanchnic area in shock. He set the problem to determine the actual loss to the circulation. He ascertained first the total amount of blood to body weight. This he estimated at 7.7 per cent., or 1/13 of the body weight. He thus established the normal standard. He then bled the animal from a large vessel; this represented the measure of efficient blood. He then drew the blood from the venous side (the right auricle), which, added to the arterial blood, made up the mobile blood. The sum of these two subtracted from the calculated total blood represented the immobile, or useless blood. In unshocked animals 24 per cent. could not be drawn and was considered immobile blood. He found that in shock produced by opening the abdomen and manipulating the intestine, 61 per cent. remained immobile. Compare this with complete destruction of the vasomotor center, which immobilized only 42 per cent. In shock the amount of circulating blood was less than in section of the spinal cord. A series of experiments confirmed these statements. This immobilization of blood took place beyond vasomotor control. Captain Marshall had made some observations in France on the hemoglobin content of blood, which seemed to support the view that oligemia was an important factor. Experiments were also reported by Dale and Macintosh with organisms of the gas gangrene group isolated from human material. The evidence available indicated a striking similarity of origin underlying the similarity of symptoms between the toxemia of gas gangrene and other shock-like conditions. Effects of the same kind were produced by other products of protein digestion,

bacterial products, etc. Mann contended that shock and hemorrhage were identical in all essential particulars. In some respects, however, most important for the purpose of the surgeon, the two conditions differed materially, as had been clearly pointed out by the British Research Committee. In hemorrhage even of sufficient severity to diminish the output of the heart and lower the blood pressure, if the case was not allowed to go too far, normal reaction might yet take place, fluid be drawn back into the vessels, and restoration be established, and this we knew might be enormously assisted by transfusion of blood, or by saline infusion. In shock oligemia was pronounced, the outgo of plasma into the tissues continuing in spite of the introduction of fluids into the blood, and only the most temporary benefit was accomplished. So long as a man was alive there was hope in hemorrhage if fluids could be introduced. So bad, however, was the picture in shock that Rendle Short declared in 1914 that it was hopeless to do anything for the shocked victim. In hemorrhage, too, cardiac stimulants had a place, but in shock they were worse than useless, until reaction could be otherwise established. Another important difference was the effect of local anesthesia in preventing shock by blocking the centripetal impulses. The treatment of shock resolved itself into measures intended to raise the blood pressure and restore the animal heat. W. T. Porter found a remarkable absence of nervous shock in the midst of the most horrible carnage, so that the psychic factor seemed to play a very small role. In the badly wounded he found the blood pressure a most valuable guide, especially the diastolic. When the diastolic pressure fell below 50 mm. the condition was very grave and resuscitation was doubtful, but when reaction could be brought about recovery was often rapid. Elevation of the lower limbs and head lowered just below the level of the abdomen was the best position. A special table was devised, which enabled him to keep the patient warm in the proper position. Saline infusion was given for temporary effect and sometimes adrenalin given in weak solution continuously was advantageous, but the saline infusion was temporary in its effect unless the blood pressure could be raised. Porter spoke highly of respiratory suction or the thoracic pump. By introducing carbon dioxide into the air breathed the chest was expanded and a powerful traction force exerted on the blood in the liver, drawing it through and establishing reaction in some very bad cases. The suggestion of Porter was simple and worthy of trial, because so easy to apply. Finally, as the alkali reserve was probably reduced in all these cases, the administration of bicarbonate of soda might be tried with advantage. Dawbarn's suggestion of bandaging the limbs employed in conjunction with the respiratory suction was valuable. This would have the effect of drawing the blood to the right heart not only from the vena cava but also from the portal capillaries. There was one danger suggested by Simonds: the section might in fat embolism draw the fatty globules from the lung to the left auricle and be then sent with fatal effect to the brain.

Injuries to the Spine.—Dr. JOSEPH RANSOHOFF of Cincinnati stated that his paper was based on the number of cases handled at the Cincinnati General Hospital within a little less than two years. There were altogether 16 cases of injury to the cervical spine, which large number indicated the frequency of lesions in this region. Six of the cases died within from 12 hours to 2 weeks. In none of these cases was a laminectomy performed. Three of these fatal cases were attended with considerable shock, and it was found that they were complicated with fractures of the skull, a complication which was far more frequent than was ordinarily supposed. In all of the cases, with one exception, the paraplegia was synchronous with the receipt of the injury. In only one case, a stab wound, causing fracture of the spinous process and body of the vertebra, did the paraplegia come on several hours after the injury, as a result of hemorrhage. There had been no displacement of the segment. In the remaining cases there were for the most part no symptoms whatever on the part of the cord or cord nerve roots of pressure on the nerves and their branches through the intervertebral foramina. Limitation of motion and some pain thereon, with a fixed de-

formity, were the only evidences of fracture which were displayed by the x-ray. He could not emphasize too strongly the value of taking the picture through the mouth. There was only one case of what seemed to be a pure dislocation, but even in this the x-ray showed a slight fracture of the body. The discrepancy between the fatal outcome and the x-ray picture was shown in many instances, because in these the x-ray showed a nearly normal spine, evidently proving the contention that the spontaneous reduction, the result of the handling of the patient, often occurred. An interesting case was one of a shot wound, which, without producing any fracture of the spine, caused contraction of the cord, particularly of the pyramidal tract, and of the gray matter in the region of the seventh cervical and first dorsal vertebrae. The ilio-spinal center was contused and followed by the typical contraction of the pupil, exophthalmos, and slight ptosis on the side of the injury. At the operation the sympathetic nerve cord was found uninjured, thereby accounting for the absence in this case of the unilateral sweating and flushing of the face, which usually attended wounds of the cervical sympathetic nerve cord itself.

The Cancer Problem.—Dr. CHARLES H. MAYO of Rochester, Minn., stated that cancer continued to be one of the greatest scourges of the human race. It was apparently on the increase among the more highly civilized people, yet might be worse than suspected among lower types of the human race through lack of examination and investigation, as was shown to be the case in cancer of animals and lower types of life. In this connection, the work of Erwin Smith was one of the utmost interest in showing cancer in plant-life. Discussion, investigation, and discovery had given control of other great life-destroying diseases, and had been most helpful in aiding in the control of cancer. The educational propaganda of Dr. Bloodgood had been of incalculable value in the prevention and early treatment of cancer in this country. The greatest advance in our knowledge of cancer had come from a study of the individual cancer cells. MacCarty believed the disease to begin in the waiting or repair cells. We thus saw how the stimulation of continued traumatism might stimulate to activity such repair cells when lack of control, differentiation, and migratory hyperplasia would place them within the cancer classification. Many writers believed there was a true fertilizing agent of the nucleated cells which gained entrance to local areas and cell intelligence for growth carried on progressive activity. Some believed this fertilizing agent was water borne. All these theories should be subject to investigation, as, after all, the essential facts concerning the cause of cancer were lacking, and yet all causes might be associated and harmonious. Nearly one-third of the cancers that affected man were found in the stomach where acidity was constant and high. The duodenum which, by right of continuity of tissue, close association with and opportunity for grafting, and apparently far more commonly affected by ulceration than the stomach, was almost never affected with cancer, which, however, spread into all other tissues around it when developed from gastric cancer. Ulcers occurred in the stomach one-third as frequently as in the first portion of the duodenum. Sixty to seventy per cent. of gastric cancers gave a history of preceding ulcer. Ulcer then was more common in the naturally alkaline duodenum. Ulcer or cancer was rarely seen in the duodenum below the first two inches. Cancer occasionally occurred by penetrating through a duct, although in the whole length of the small intestine it occurred but twice, to ninety-eight times in the large bowel. The colon was frequently affected with cancer because here again we had acidity, and seventy-five per cent. of the tumors were located in the fixed and tissue-surrounded portion of the colon, which retained the dry and harder contents as a traumatic agent. The essential of cancer was uncontrolled hyperplasia developed in repair types of nucleated cells which grew most favorably in acid fields.

Cure of Hernia in the Male.—Dr. HENRY O. MARCY of Boston said that owing to the very careful study of an exceptional case of congenital hydrocele, he was led to make, when an assistant to Dr. J. B. S. Jackson, Professor of Pathology in the Harvard Medical School, careful anatomical and pathological dissections of the

inguinal canal, and early arrived at the conclusion that the reason all men were not subjects of hernia was because of the normal obliquity of the inguinal canal which caused the intraabdominal pressure to be exerted at right angles to its long axis. He was the first American pupil of Lord Lister in Edinburgh, before his teachings had received any recognition except in criticism. Lord Lister at this time had never used buried animal sutures, but had ligated arteries in continuity, closing an aseptic wound, followed by primary union. It seemed to him a logical deduction that it would be equally safe and wise to reconstruct the various injured tissues of the body and, when well vitalized, restore their normal function. His careful studies in the lower animals demonstrated the safety and wisdom of such procedures. This led him to believe that the inguinal canal could be safely reconstructed to its normal obliquity, and as a consequence inguinal hernia in the male was safely and permanently cured. Little by little he was led to the aseptic application of aseptic sutures made and maintained aseptic for the reconstruction of a great portion of the body. His first operations for the cure of hernia were in 1870. Since 1882, when he first obtained a supply of tendon from the tail of the kangaroo, he had used no other suture material. In aseptic well vitalized structures, thus coated and protected by a seal of iodoform collodion, primary union was the rule. Usually the only dressing applied before the patient left the surgery was the iodoform collodion, reinforced with a few fibers of absorbent cotton. In the different conditions and necessary modifications which might be called the operative technique, the one essential instrument necessary was a full curved needle, with an eye near the point, which permitted the use of a double continuous suture. Briefly the advantages were: minimizing the amount of suture material buried, the even coaptation without the constriction of the parts involved, and the use of a single knot in permanently holding the parts in apposition. The carrying of the thread by the needle with the eye near the point was the first primary necessity in the invention of the Howe sewing machine, which gave a continuous double suture, not unlike that used from time immemorial by the shoemaker. For years the Howe family was under his supervision professionally and he familiarized himself with this basic principle of mechanical sewing. He made repeated efforts to invent a needle carrier that would apply the Howe lock-stitch for surgical uses, but in this he did not succeed. After having been instructed by a shoemaker, in his method of sewing leather, he devised the needle known by his name.

Subparietal Rupture of the Intestines.—Dr. RANDOLPH WINSLOW of Baltimore said that subparietal rupture of the intestines was a comparatively rare injury. The small intestine was much more frequently ruptured than the large, and the ileum was the usual seat of the laceration, though the jejunum and duodenum were also injured in a progressively diminished ratio. The causes of the rupture might be either direct blows on the abdomen, whereby the bowel was compressed against the bony structures, or a force which caused bursting of the distended viscera by a sudden displacement of their gaseous or liquid contents. While direct violence was the common cause of the injury, it was known that indirect violence might also cause this lesion, such as a fall upon the feet or the buttocks. The symptoms of a subparietal rupture were very similar to those of a penetrating wound or a perforating ulcer of the stomach or intestines. There was a history of a blow or other traumatism on the abdomen, followed usually by severe pain, rigidity of the abdominal walls, tenderness on pressure, vomiting, increased frequency of the pulse, with soon an elevation of temperature and a high leucocyte count. There might be marked tympanites and obliteration of the liver dullness, but these signs were by no means constant, nor was shock a constant or a reliable symptom. The patient, however, had received a mortal injury and he generally showed it in his facies. The symptoms would depend somewhat upon the extent of the injury, a small opening might give exit to the intestinal contents slowly, and the inevitable peritonitis might not develop as rapidly as when the laceration was more extensive. As a subparietal laceration of the small intestine was always fatal, as far as known, when un-

operated on, it was of the utmost importance that a diagnosis should be made at the earliest possible moment. Contusions of the abdominal wall might present somewhat similar symptoms, but they were not usually so pronounced and tended to subside, while those of a rupture became progressively more accentuated. In any case of doubt it would be safer to open the abdomen and ascertain the extent of the lesions than to wait in the hope that no serious injury had occurred. While the general subject of subparietal injuries of the intestines was of great interest, his attention had been especially directed to the rôle of a hernia in the production of intestinal lacerations, since two such cases had come under his care in the past two years. In these cases blows upon reducible inguinal herniæ were followed by rupture of the intestines.

A New Operation for Colon Stasis Modified from Rovsing's, with a Report of Twenty-eight Operated Cases.—Dr. GASTON TORRANCE of Birmingham, Ala., stated that the only step in this operation which exactly duplicated Rovsing was the three rows of sutures put in the anterior surface of the stomach for elevation and fixation of the stomach, and his claims for a new operation were based on (1) the preservation of the omentum intact; (2) the actual suture of the colonic bands to the stomach; (3) the lowering of the flexures, and (4) the elevation of the liver by pulling the suspensory ligament up through the fascia and suturing it as if done in the Gilliam operation. The first thing to be done was to examine the cecum and if it was much dilated to narrow it by suturing two bands together up to the hepatic flexure. The appendix should be removed. The stomach was then brought up and three rows of strong linen sutures were put in across the anterior surface, care being taken not to go too deep and to avoid wounding any blood vessels. When the x-ray showed a very high attachment of the flexures, and especially the splenic, this should be pulled down and incised and dissected down far enough to prevent any angulation after the colon is raised. A point was selected on the ascending colon, and sutured to the stomach a few inches below the cardia. The band on the lower border of the colon was found and a mid point was selected and the omentum was held up and by transmitted light this point on the colon was sutured to the stomach through the omentum midway between the two sutures mentioned above (heavy linen is used)—a midpoint was again selected on the two halves of the colon and stomach and points were again selected between these sutures until all of the slack was taken up in the colon (which contracted down so that it fit snugly to the lower border of the stomach) and until the sutures were within at least half an inch of each other. As the mesentery extended down almost to this band, he found it narrowed the colon somewhat by suturing it to the stomach and formed an apron which held the colon up in place and gave a smooth surface beneath the mesentery. The omentum had not been injured in the least and fell down in its normal place and prevented any adhesions. The three stomach sutures which were left long were now threaded on a Riverden needle and brought out through the abdominal wall near the border at the ribs on the left side and a little nearer the midline and at a lower level on the other side. These sutures were drawn up tightly and clamped close to the skin and the abdomen was then closed, and the sutures were then tied over a tin box about 3 inches square wrapped in gauze. The patients were kept in bed four weeks and the sutures removed in from three to four weeks. He operated in 28 cases by this method, with 21 cures, 2 improved, one not heard from. Four patients died, none of them in consequence of the operation. One patient died of pneumonia two weeks after operation, one died of acute dilatation of the heart one week after operation, one died four weeks after operation, probably from an acute exacerbation of pellagra, and the other case of inanition two weeks after operation. Two cases had been operated upon four years, four cases three years, thirteen cases two years, three cases one year and two cases six months. Twenty-six cases were in women and two cases in men. In eight cases the ligament operation was done on the liver and the left lobe of the liver was sutured to the diaphragm in one case. The cecum was plicated in eight cases.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 6, 1917.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

The General Diagnostic Study by the Internist.—Dr. LEWELLYS BARKER of Johns Hopkins Hospital, Baltimore, made this address, which he illustrated with lantern slides. He said that when he had been honored with an invitation to address the New York Academy of Medicine he thought over subjects that might be of interest and it occurred to him that he had heard the statement made that if a man could be interesting about anything at all it was about the work that he was doing every day. The work they were doing was very interesting to those who were doing it and it seemed that it might also be interesting to others to know just how they were working. He had therefore decided to show by means of lantern slides the method he was using in making a diagnosis. This method consisted in the application of reflective thinking to medicine and to the solution of diagnostic problems. It was the province of the internist to survey the body as a whole; the field of the specialist was limited to a single part of the body. The internist must know enough about each specialty to judge of the significance of the reports that came from the specialist. He considered the surgeon a specialist, a specialist in therapy. The internist was to study the patient as a whole, and when a tentative diagnosis had been made experts in special domains of medicine or surgery might be called in. In the application of the process of reflective thinking to the making of a diagnosis five steps were involved. *First step*—Each patient should be regarded as a special problem requiring scientific study for its solution. No "snap diagnosis" should be made. There should be a registration of symptoms with a suspension of judgment until sufficient facts were obtained upon which to base a diagnosis, though, of course, pain should be relieved or a surgical emergency attended to. There should be a realization that a situation that was apparently simple might be complicated. There should also be a realization at this stage that the diagnosis was vague and a complete history of the case should be recorded. The *second step* consisted of a localization and definition of the diagnostic problem. This included: (a) collecting the facts in the case, (b) summarizing them, and (c) correlating them. Collecting the facts included anamnesis, general physical examination, and the application of all the laboratory tests, x-ray examinations, etc. The laboratory tests included examination of the cerebrospinal fluid, tests for tuberculosis, including excision of a gland or small nodule, blood chemistry, and a bacteriological culture, tests for renal function, metabolic studies, protein sensitization tests, pharmacodynamic tests, electrocardiograms, sphygmographic tests, exploratory punctures, animal inoculation, etc. The examination should include the eyes, ears, nose, throat, and teeth as well as the esophagus and the genitourinary tract and an examination of the nervous system. *Third step.* The speaker in sending a patient to a specialist for an examination sent the following note: "Dear Doctor:—Be kind enough to examine in your domain and send me the report and oblige." He did this because the specialist was likely to think the patient's trouble was in his domain. Dr. Barker cited an instance in which he had sent a patient to some four or five specialists and each one located the trouble in his special domain, and he said this was no unusual occurrence. He did not wish the specialist to make the diagnosis or express his opinion to the patient until all the evidence was collected. The examination should include an x-ray examination. In this opinion a good teleoroentgenological examination gave more information than palpation. While it was important to have these various examinations made by the specialist it was important for the internist who was making the general survey to have sufficient general information to enable him to choose the right one. The *fourth step* consisted in applying the deductive process of reasoning and making a systematic inference from the facts, a rational elaboration of the data that had been obtained. The *fifth step* was corroborative. It consisted of a further observation for the purpose of testing the suggestions

and inferences leading to the conclusions as to whether the internist believed or disbelieved in the correctness of the diagnosis at which he had arrived. In making the physical examination, Dr. Barker said he always considered weight an important factor to be taken into account. He allowed 110 pounds for five feet in height and five and one-half pounds additional for every additional inch in height. This would be found to be a good guide as to whether the patient was under or over weight. Knowing whether a patient was under or over weight gave a clue to the disease or diseases that one might expect to find. It sometimes happened that two plausible ideas in regard to the diagnosis might be unified and absorbed into one. In arriving at a diagnosis by this, or in fact any method, there was no doubt that experience helped greatly. The finished diagnosis was thus a combination of observation, inference, and reasoning. The trained diagnostician knew how far it was advisable to carry each step in each case. It might not be necessary to carry out all of the examinations in every case. To carry an examination too far in some cases might be foolish, in others an omission might be disastrous. Dr. Barker completed his exposition by taking several cases up in detail and applying the method outlined to illustrate how in an individual case a correct diagnosis was arrived at.

Dr. CHARLES L. DANA expressed his appreciation of Dr. Barker's address and said he thought it furnished an admirable and stimulating ideal of the way in which one should work out a diagnosis. As a neurologist he rather objected to being classed with those who took a narrow view of their specialty; in fact he had frequently taken the same position with reference to the internist and the surgeon that Dr. Barker had taken in reference to the neurologist. The neurologists quite agreed with Dr. Barker as to what should be done in order to arrive at a diagnosis and the presentation of what should be done was so complete that he could find no point to criticize. But it had occurred to him, and he supposed to all those who had had long experience in dispensary work, to wonder how a physician in an out-patient department of a dispensary could apply such a thorough diagnostic system when he was called upon to treat sixty patients in two hours. It seemed to him that Dr. Barker's presentation drove home to them the fact that such examinations as he had described should be more frequent and cheaper. The problem of collaborating the results of physical examination, laboratory data, and roentgenological examination was one they would have to solve. It was perhaps the part of social workers and of those interested in social progress to devise a method of securing more group work by which this complete and admirable system of diagnosis could be carried out.

Dr. SAMUEL J. MELTZER said that he could not claim to be an internist since for many years the laboratory had been his working place. It happened, nevertheless, that even now he saw a patient occasionally. He found that it took him more than an hour to come to a definite conclusion in a single case and even that without employing the scientific and complex method advocated by Dr. Barker. The majority of the large audience present consisted of practitioners who were now in the same position that the speaker was thirty years ago when he often saw thirty and more patients a day. Were they to employ the methods recommended by Dr. Barker? An illustration would best convey what he wished to say. In 1888, he took his assistant, a well-informed man, to see a patient with him; he desired to see him making the examination and arrive at a diagnosis. The examination was made in as thorough a manner as the methods of those times permitted. The patient had a temperature of 104° F. and a pulse of over 130; but his predominating complaint was excruciating backache. In their consultation his assistant stated that he could not localize the cause of the disease, but it occurred to him that severe backache was a symptom present in smallpox. Dr. Meltzer said he was dumbfounded; he went back to the patient and put his finger on the region of the right submaxillary gland to which the patient responded with evidences of pain. By looking into the throat it was found that the right tonsil was swollen and dotted with spots. The diagnosis was, of course, tonsillitis. His assistant wished to know what made him go directly for the sub-

maxillary gland. His answer was that soon after looking at the patient he noticed that he feared to swallow and that when he had to do so it was followed by contortions of the right side of his face, that it was the beginning of winter and that there were many cases of tonsillitis in this vicinity. On the other hand, the idea of smallpox did not even occur to him although he was well aware that many adults who suffered from this disease complained severely of backache. Why had he not thought of the possibility of this disease and tried to exclude it? Because the mental process which he employed in making a diagnosis was very simple. He thought first of those diseases which at a certain season and in certain localities occurred eighty-nine times in a hundred, and he went straight for their manifestations. Only when he failed did he begin to pay attention to the remaining one or two percentage of possibilities. This method might appear as very unscientific, and he would confess that his main interests always had been and still were in scientific methods and investigations. But at the bedside he was still a practitioner; he did not look for the exceptional and he was carefully on his guard against notions which, although they might possess a scientific nimbus, were only of an ephemeral instructive character which did not possess a permanent practical value. The history of medicine was full of such phenomena. In brief, for the vast majority of cases a correct diagnosis was more likely to be made by a trained physician possessing a critical mind who went straight for the most probable point than by one who attempted in all cases to reach that point by the process of exclusion of all other possibilities—which rapidly became more and more numerous.

Dr. M. ALLEN STARR said he shared Dr. Dana's indignation in being relegated to the lowest level of the diagnostic ladder. But, speaking more seriously, he thought such coordinated work as Dr. Barker had described was possible only in a well organized hospital or dispensary. All virtue in this respect did not lie in Baltimore; there were three hospitals in New York where combined work of this character was being carried out. As the consultant in neurology he knew that work of this character had been carried out for 20 years at the Presbyterian Hospital. At the present time at the Vanderbilt Clinic there was an attempt to correlate the work of different specialists by a system of cards by which the patient was transferred from one department to another and in this way a very complete record of the case was obtained. The method that Dr. Barker had described and displayed was really the plan studied in Germany, and was perhaps one of the few good things that had come from Germany. Nothnagel in Vienna employed this careful method of making examinations and taught it. Dr. Starr said he thought all had been impressed with the necessity of *not* making a snap diagnosis and *not* omitting to make a very careful examination.

Dr. EMANUEL LIBMAN said it was to be understood, he believed, that Dr. Barker, in presenting his scheme, did not mean that it was intended for simple cases in which the diagnosis could be cleared up rapidly; he was, no doubt, referring to cases difficult of diagnosis and particularly to those which came to the internists from a distance, and which must be studied in great detail. Frequently some of the special examinations that were not absolutely essential were demanded by the patient or his physician. At times when cases came to one from out of town, he must have unnecessary x-ray examinations made, because the physicians studying the case would not regard the report complete without such an examination, and would then send the case elsewhere to have the x-ray examination made. Often a complete study of a case in such a fashion as Dr. Barker had described would be found of great value in discovering conditions existing in the patient apart from the symptoms from which the patient was suffering when he came for examination. In order to investigate thoroughly cases coming to our hospitals and dispensaries for study, it would be necessary in the future to have our institutions reorganized on the plan of the Mayo Clinic, having a chief under whom a large group of men worked and examined the cases. This was not easy to introduce in many of our institutions at the present time because not all men connected with the hospitals

could fit into a diagnostic group or groups. Until the trustees of hospitals grasped the situation and had the courage to reestablish their staffs on a proper basis, such diagnostic groups would have to be privately organized. Dr. William J. Mayo had stated to him that he believed that the head in all general hospitals should be an internist with a staff of men working under him, and that the patients should be presented to the surgeon for his opinion and action after the preliminary investigations had been carried out. Dr. Barker would be glad, he was sure, to hear that Dr. Mayo agreed with him in considering surgery a branch of therapeutics.

Dr. RUFUS I. COLE said that one of Dr. Dana's remarks had made an impression on him, and that was that it was a far cry from the conditions under which a man worked in a dispensary and the method Dr. Barker employed, and with this was associated the thought that the economic advantage lay with Dr. Barker's method. The quick way of making a diagnosis was, after all, the expensive way, for when one saw a hundred patients in a couple of hours he was unable to do them justice and they returned again and again and went from one dispensary to another; if the same amount of money spent in this way were expended in actual diagnosis a saving would result in the long run. This plan of making a thorough diagnosis would require organization, but in the end would be cheapest.

Dr. VIRGIL P. GIBNEY said that while listening to Dr. Barker describe this method of making examinations the thought had come to him and probably to others, "How much would this cost?" Very often one had a patient and spent a great deal of time over an examination, only to find that he wanted a little special advice or he wanted an x-ray. The question came up how much the patient could stand financially. The roentgenologist was not satisfied until he had taken x-ray plates of the greater part of his anatomy and the patient began to wonder how expensive a doctor he had consulted. A negative report led one to order a bismuth meal and another x-ray was necessary in order to determine whether the patient had intestinal stasis, the expense of which would range from sixty to eighty dollars or more. The doctor-in-chief found that these extraordinary charges so dwarfed his own that his bill had not made much impression on the patient, and when he wanted advice again he would go somewhere else. Dr. Gibney said that he, specialist that he was, appreciated the need of a thorough examination in his line of work such as Dr. Barker had described. He thought it a good plan for a young man starting out in the practice of medicine to spend some of his time, while waiting for patients, studying at the clinics of different specialists and making of himself a universal specialist. He should take a course at a neurological clinic, at an ophthalmological clinic, etc., and in this way he would get a grasp of the situation as a whole and would not need quite so much help from the different men specializing in other branches. Dr. Gibney then related an instance showing the position in which one often found one's self. A gentleman had come to him a few years ago from a neighboring State with arthritis of the elbow and he had treated the case by immobilization. After a time the patient said to him that he had had an episode in his early life that might throw some light on the situation; he gave a history of gonorrhea and the speaker then sent him to a genito-urinary specialist, to the x-ray laboratory, and to a gastrointestinal specialist (an internist). After a time he had the patient practically cured of his arthritis so that he was able to beat his doctor at golf. This very day he had returned and said his elbow was not as well as it had been, and he had sought advice in New Haven, being "put through the mill." Not getting a satisfactory result, he sought advice in Boston, where he met a distinguished member of his own (Dr. Gibney's) specialty. The advice was to remain in Boston for observation and subsequent treatment. This patient really came to the speaker to get advice as to whether he should go to Boston for his cure or come to New York. Naturally the advice was to come back to his "first love," and he told the patient a story heard from the late Dr. Knapp: A doctor from Boston came to him for advice about a serious lesion of the eye. Dr. Knapp made the diagnosis and told the patient to go

down to his private hospital for an operation. This was too much for the Boston doctor-patient and he said: "I like that; haven't we as good surgeons in Boston as you have in New York?" "No," said Dr. Knapp, "and you never will have, for medicine and surgery are like commerce, they seek the best market." Needless to add, the patient resumed treatment in New York.

Dr. WILLY MEYER said that everyone must have been impressed with the value of this method of diagnosis and especially with the system whereby everything was written down in black and white and followed in every particular. The surgeon was frequently called upon to assist in the diagnosis of borderline cases. Taking the three cavities, the cranial, the thoracic, and the abdominal, the neurologist usually made the diagnosis of a cranial condition, but the surgeon was called upon to assist in the diagnosis of thoracic and abdominal conditions. They would certainly all agree that during the last ten years the x-ray had brought them much assistance in diagnosing these conditions, so that he need not dwell upon that point. But there was another point that he would like to mention, and that was that they had made great progress in the diagnosis of gall-bladder and duodenal conditions by means of the Einhorn duodenal bucket, which enabled one to obtain the secretions of the liver and pancreas. With all the means now available as aids to diagnosis it was a pleasure to have a borderline case gone over by all the specialists before an attack was made by the surgeon. The written-down system was being used here in New York and the same lines were followed that had been described by Dr. Barker. The patient in the ward and the private patient were getting the benefit of this system. The patient who was not getting it was the semi-private patient who was unable to pay the specialists and objected to going into the ward as a charity patient. It had been his experience that, when a patient was unable to pay the full price asked by the specialists, the specialists had been willing to reduce their prices. The problem we had to solve was that of the semi-private patient. The diagnostic clinics that had been started here with a great deal of opposition would have to solve the problem, and it seemed probable that they would have to establish separate buildings for the care of semi-private patients and that a combined group of men would have to unite to care for them.

Dr. BARKER, in closing, said that Dr. Meltzer had spoken of finding the most important thing in each case and going directly at that. It should be remembered that what seemed to be the most important thing was not always the actual cause at the basis of the trouble. He spoke of the impossibility of giving thirty patients a day such a thorough examination. Such an examination might not be necessary in all of the thirty patients, but among that number there might be two or three who should be studied in this way. The general practitioner should sift out these few who needed this special study from the larger number who were suffering from minor ailments and did not require it. With reference to Dr. Dana's remarks, they all knew that many neurologists were also internists and that Dr. Dana had a wide reputation as an internist, but the point he wished to make was that the survey of the body as a whole was the work of the internist. Dr. Starr had spoken of this work as being possible only in hospitals and dispensaries. These cases that were discussed this evening were simply office cases. Such cases came before the internist in his office and the question was how he was to do this work. Certainly the work in hospital helped to develop the method and it was impossible to develop it without hospital experience, but it was still possible to apply the system in office work. Dr. Cole's point that the expensive way of diagnosing a case was the cheapest in the long run was well taken; in obscure cases it would save a great deal of money if a proper diagnosis were made in the beginning. Dr. Libman spoke of the fact that a thorough diagnosis brought out the little things that might be overlooked; that was certainly true. Dr. Gibney spoke of the cost of many special examinations, but that was a problem which must be worked out. He knew of a case now that was diagnosed as a neuritis and was being treated as such when in reality the

patient had an arthritis. The failure to make a proper diagnosis and treat this patient properly had resulted in a loss of time and money. Dr. Starr spoke of the young man getting a little training in each of the specialties. It was impossible for any one man to keep up with the advances that were being made in all of the specialties; the general practitioner had to remain dependent upon the specialists to help him out. Dr. Meyer spoke of the borderline cases and of the cooperation between physician and surgeon in diagnosing such cases. There was no such thing as a surgical diagnosis or a medical diagnosis; it was a question of diagnosis as a whole, and it made no difference who captained the procedure, whether the neurologist, the surgeon, or the medical man, so long as he possessed the general knowledge, the work was well done, and the correct diagnosis arrived at.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, January 9, 1918.

DR. MOSES BEHREND IN THE CHAIR.

The Problem of Neurotics in Military Service.—Dr. ALFRED GORDON called especial attention to a class of men, very little understood, whose manifestations were regarded as spurious, imaginary, and consequently of too slight importance to be considered. He used the general term "neurotics" to cover the vast field of individuals whose mental makeup was such that at any time during life, under the influence of the least emotion, mental and physical disabilities might develop, rendering them useless in the community. (See page 234.)

Report of the Tuberculosis Examining Board at Al-lentown Camp.—Lieutenant RAE S. DORSETT read this report. He said the personnel of the Board consisted of Drs. John J. Robrecht, William S. Wray, Robert G. Torrey, Louis Jurist, Albert E. Blackburn, and Rae S. Dorsett. Work was begun on July 25, 1917, and finished during the first week of September. Two hundred and twenty officers had been examined, of whom five were found to have active tuberculosis. Of the 5,293 men examined 18 had active tuberculosis. At the time of its work the Board could simply recommend to the Disability Board at the camp. The Disability Board, with the hope of improvement in the condition of the men, had retained in service some recommended by the Examining Board as physically unfit. In four instances, however, such improvement was not realized and the men were discharged. The Examining Board could not but feel that had its recommendations been promptly accepted some expense to the Government would have been saved.

Examination of Men at Fort Niagara and Gettysburg.—Lieutenant AUGUSTUS A. ESHNER related his experience as a member of a tuberculosis and cardiovascular board in the examination of men at Fort Niagara and Gettysburg. In the First Reserve Officers' Training Camp at the former place 2,000 men were examined, and in the Second Camp approximately 2,200, including, in addition to candidates, a certain number of National Guardsmen, artillerymen, quartermasters' men, men on detached service, and others. Only a few cases of active tuberculosis were found, and but a small number of disqualifying cardiovascular diseases. At Gettysburg more than 10,000 enlisted men were examined, including 29 cases of active tuberculosis and 62 cases of disqualifying cardiovascular disease. Dr. Eshner called special attention to the large number of cases in which a murmur was audible in the third left intercostal space near the sternum, often transmitted obliquely upward to the left, and which he was disposed to attribute to physical changes of an undetermined character induced in structures at the base of the heart in consequence of the great physical activity to which the men were subjected in the course of their training. Also he expressed the view that a third sound or even a well-developed presystolic murmur could be generated as a result of temporary or permanent derangement in the relations between the left auricle and ventricle and the mitral orifice, whether in consequence of actual antecedent disease or from abnormal functional demands.

Report of the Examination of the Sixth Infantry National Guards of Pennsylvania in Philadelphia in August, 1917.—Dr. HERMAN B. ALLYN reported that the examination was part of a general examination of all the National Guard stationed in Philadelphia. It was in charge of a Tuberculosis Board, of which Captain, now Major Siner, was president. The writer and Dr. John A. O'Connell were assigned to the examination of that portion of the Sixth Infantry stationed in Philadelphia. Every one in authority had been ready to help in the work and had received the board most cordially. Instructions to the board were explicit; they were to recommend the rejection of cases of active tuberculosis, as determined by the presence of râles, but were to retain in the service the men having old or quiescent lesions. The feeling was expressed that perhaps a wider latitude allowed the examiner would have resulted in weeding out some who were not likely to render good service in the army. Osler's experience with the British army, it was observed, had been that those with long, narrow chests, the mouth breathers, and the neurasthenics filled the hospitals. Fortunately, in Dr. Allyn's opinion, the Examining Board had its own Disability Board so that those recommended for discharge by the Board were, so far as known, all dismissed from the service. Dr. O'Connell and Dr. Allyn examined 766 men, among whom they found 11 cases of tuberculosis and 25 cases of heart disease. Some of these were recommended for discharge and others were referred to the regimental surgeon. The belief was expressed that it would be better in any subsequent examination to keep a record in duplicate on filing cards of every man in whom anything abnormal was found.

Report of Examinations in Camps and Armories in Philadelphia, Gettysburg, Washington, and Texas.—Captain A. C. MORGAN reported that a Board of Examiners for tuberculosis and cardiovascular disease had examined 6,308 men in Philadelphia and vicinity during August and September, 1917. Thirty-two cases of tuberculosis were found in this number, only 9 of whom were discharged from the army, the remainder showing small arrested lesions with otherwise good physical condition, and being considered to be of military normality, were therefore recommended for retention in the service. Fourteen cases of valvular heart disease, two cases of adherent pericardium, and one case of chronic nephritis, with marked arterial hypertension, were discharged from the service. A statistical report of other conditions found by the writer, in association with Dr. T. Mellor Tyson, in a further study of the First Pennsylvania Regiment Infantry, was read. The work done by Captain Morgan at Gettysburg was in the nature of a study of recalled cases and also of a review of recruits that had been sent down from Harrisburg and other recruiting stations. On one occasion over 50 per cent. of the recruits sent down were rejected for various military reasons. The writer emphasized the point that herein lay a great weakness of the army. If skilled and highly trained medical men were to pass on applicants at recruiting stations it would decrease in large measure the urgency of need for specialists in the army. Reference was made to the work of inspection and observation of men who were ordered to the Walter Reed Memorial Hospital. Explanation was given in detail of the technique insisted upon by Colonel G. E. Bushnell to determine the presence of moist râles in the earlier state of activity of the lungs. When persistent moist râles were present negative sputum examinations and x-ray findings are not to be given preference, this sign being deemed to be of sufficient importance to clinch the diagnosis of active pulmonary tuberculosis and the dismissal of the subject from the army. The work done at Waco, Tex., was then reported. Nearly 12,000 men were examined, coming from Wisconsin and Michigan. A remarkable finding was the thousands of cases of hyperthyroidism, some of them being of very large size. Many of them showed cardiac murmurs, a few had tremors and tachycardia, while but very few presented scars from operative interferences. Five hundred and ninety cases were referred to the cardiovascular board. While no classified table was made, it was noted that there seemed to be an unusually large proportion of cases of aortic regurgitation. Nearly all of them presented a history

of having suffered from acute articular rheumatism. Twenty-seven cases were referred to the psychopathic department, 25 to the orthopedic, and 45 to the nose and throat departments. Five cases of asthma were discovered and a positive opinion expressed that subjects suffering from this affliction should be absolutely excluded or discharged. It was pointed out that in army circles when one was expecting orders or information he should be content with the apparent slowness of various procedures and to use the army phrase, "Sit tight" until orders came through.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting held December 21 Dr. FRÉDÉRIC H. LEAVITT presented "A Patient Showing Dwarfism with Congenital Speech-Defect." The patient was a girl, five years and two months old, born at term, with healthy parents and brothers and sisters. She weighed two and a half pounds at birth, and now only 22½ pounds, while her height was 33 inches. Apparently she heard, and she obeyed instructions of varying grades of complexity. She spoke only a few words as a rule, although it was said that she spoke more freely in the presence of her nurse and of children with whom she played.

Dr. FRANCIS X. DERCUM presented "A Case of Myositis Ossificans Progressiva." The patient was a girl, nine years old, in whom some stiffness of the back had been noted for several months. A swelling appeared in the left scapular region, and this was incised, but without any discharge. Gradually, firm deposits took place in muscles in various parts of the body, and x-ray examination confirmed the conclusion that these were bony in character. The thumbs and the great toes were all diminutive.

Dr. DERCUM presented also "A Case of Brain-Tumor," occurring in a man, perhaps 32 years old, who had had an injury (fracture and dislocation) of the right forearm early in life, and who suffered several nervous breakdowns. Over a period of about six months he had presented headache, somnolence, vomiting, relaxation of the features, impairment of memory and imperfect speech. Neither the blood nor the cerebrospinal fluid exhibited evidence of syphilis. There was no astereognosis. Under observation improvement ensued, but there was persistent complaint of pain over the left frontal region, with some weakness of the right lower extremity, while the left palpebral fissure was the narrower. Hearing, smell, and taste were normal. The tongue was protruded slightly toward the right. Increased knee-jerk, ankle-clonus and Babinski reflex were at times noted on the right. Ophthalmoscopic examination disclosed marked optic neuritis on the left with a lesser degree of disorder on the right.

Dr. JAMES HENDRIE LLOYD presented "A Preliminary Note on a Case of Word-Deafness, with Word-Blindness, Agraphia, Hemianopsia, and Astereognosis." The patient was a man 60 years old, who was run down by a motor truck, and who could tell little about himself. He could hear, but apparently he did not comprehend what was said to him. There seemed to be loss of vision in the right visual fields. In the left fields the man could see, but seemed not to be able to read. There was inability to write with the right hand and an attempt at mirror-writing with the left hand. There was no motor aphasia, as the patient could speak plainly, although he did not always speak logically. X-ray examination disclosed a fracture of the orbital plate of the left frontal bone. There was a coarse jerky tremor of the right hand. The knee-jerk was increased and the Babinski reflex was present on the right. The conclusion was reached that there had been a lesion of the left temporosphenoidal lobe, a hemorrhage or a contusion perhaps with softening.

Dr. ALFRED GORDON presented "A Case with Persistent Contracture of the Toes and Fingers on the Same Side of the Body." The patient was a woman, 51 years old, who for three and a half years had plantar contracture of the last three toes of the left foot and for a somewhat shorter period a similar flexor contracture of the three last fingers of the left hand. The left knee-jerk was exaggerated. There were no other motor phenomena, no sensory disorder, no psychic manifestations, no emotional disturbance. The conclusion was

reached that the condition was either hysterical or a lenticular condition causing extrapyramidal tract disorder. Dr. Gordon was disposed toward the latter view. He proposed to apply corrective splints to the affected parts in the hope of overcoming the deformity and disability.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

PRACTICE OF MEDICINE. By THOMAS KIRKPATRICK MONRO, M.A., M.D. 1045 pages. Illustrated. Price, \$6.00. Published by C. V. Mosby Company, St. Louis.

THE ROAD TO A HEALTHY OLD AGE. By T. BODLEY SCOTT. 190 pages. Price, 4s. 6d. Published by T. Fisher Unwin, Ltd., Adelphi Terrace, London.

HANDICAPS OF CHILDHOOD. By H. ADDINGTON BRUCE. 310 pages. Price, \$1.50. Published by Dodd, Mead & Company, New York.

A COMPEND ON BACTERIOLOGY. By ROBERT L. PITFIELD, M.D. Third edition. 279 pages. Illustrated. Price, \$1.25. Published by P. Blakiston's Son & Co, Philadelphia.

MEDICAL WAR MANUAL, No. 3, MILITARY OPHTHALMIC SURGERY. By ALLEN GREENWOOD, M.D., G. E. DESCHWEINITZ, M.D., and WALTER R. PARKER, M.D. 115 pages. Illustrated. Price, \$1.50. Published by Lea & Febiger, Philadelphia and New York.

TRAINING AND REWARDS OF THE PHYSICIAN. By RICHARD C. CABOT, M.D. 153 pages. Illustrated. Price, \$1.25. Published by J. P. Lippincott Company, Philadelphia and London. 1918.

STATE BOARD EXAMINATION QUESTIONS AND ANSWERS OF THE U. S. AND CANADA, fifth edition. 973 pages. Price, \$2.50. Published by William Wood and Company, New York City.

A TREATISE ON REGIONAL SURGERY, edited by JOHN FAIRBAIRN BINNIE, A.M., C.M., F.A.C.S. Volume III. 830 pages. Illustrated. Price, \$7.00. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia.

PROCEEDINGS OF THE ELEVENTH ANNUAL MEETING OF THE ASSOCIATION OF LIFE INSURANCE PRESIDENTS, held in the Hotel Astor, December 6 and 7, 1917, New York, N. Y. 181 pages.

MEDICAL WAR MANUAL, No. 4. MILITARY ORTHOPÆDIC SURGERY. Prepared by the Orthopædic Council. 240 pages. Illustrated. Price \$1.50. Published by Lea & Febiger, Philadelphia and New York.

AN ACCOUNT OF THE PRINCIPAL WORKS OF THE ATREYA SCHOOL OF MEDICINE, WITH THEIR CHRONOLOGY. By KAVIRAJ BIRAJA CHARAN GUPTA KALVIBHUSHANA. 66 pages. Published by P. S. Gupta, 44 Beadon Street, Calcutta.

AN INTERNATIONAL SYSTEM OF OPHTHALMIC PRACTICE. Edited by WALTER L. PYLE, A.M., M.D., Philadelphia. MEDICAL OPHTHALMOLOGY. By ARNOLD KNAPP, M.D. 509 pages. Illustrated. Price, \$4.00. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

DISEASES OF THE DIGESTIVE ORGANS, WITH SPECIAL REFERENCE TO THEIR DIAGNOSIS AND TREATMENT. By CHARLES D. AARON, Sc.D., M.D. Second edition, thoroughly revised. 818 pages. Illustrated. Price, \$7.00. Published by Lea & Febiger, Philadelphia and New York.

A COMPLETE SYSTEM OF NURSING. By A. MILLICENT ASHDOWN. 746 pages. Illustrated. Price, \$5.00 net. Published by J. M. Dent & Sons, Ltd., London and Toronto; New York; E. P. Dutton & Co.

DÉCOUVERTE DES VAISSEAUX PROFONDS, VOIES D'ACCESS LARGES. Par J. FIOLE et J. DEIMAS. 119 pages, Illustrated. Price, 5 francs. Published by Masson & Cie., Paris.

LES LÉSIONS DU CORPS THYROÏDE, DANS LA MALADIE DE BASEDOW. Par GUSTAVE ROUSSY. 133 pages. Illustrated. Price, 3 francs. Published by Masson & Cie., Paris.

Miscellany.

Bread Poisoning.—In past times wheat flour often reached the consumer admixed with poisonous grains which grew as weeds in the wheat field; with worms; with fungi, and finally with chemicals used to "doctor" spoiled wheat. Today such admixture is rare. These adulterations were not suspected until the development of toxic symptoms in the consumer, although the bad look and taste of the bread sometimes gave warning. Of grains which were mixed with wheat may be mentioned a form of darnel which gives rise to so-called temulentism, literally drunkenness. Those who ate of bread containing much darnel suffered from vertigo, diplopia, speech disturbances, somnolence, etc. Plicque in the *Journal de médecine et de chirurgie pratiques* for September 10 ascribes this intoxication to an essential oil which should be driven off by baking. This may account for the fact that in this country darnel is no longer regarded as toxic. The black grains of the melampyrum, known as cow wheat (although not a grass), sometimes are found in wheat and cause a general intoxication if present to the extent of 10 per cent. The bread is unsightly, bitter, and nauseating. A form of smut, responsible for so-called smutty wheat, contains definite toxic substances, which give rise to enteritis and hemorrhages from the bowels. The bread is blue-blackish with an acrid taste. Mildewed wheat (brown rust) has an odor like that of spoiled fish and the bread baked from it is of a dirty gray color and fetid, while red rust gives rise to reddish, sour, and irritating bread. Worms in wheat (*anguilula*) rob the grain of its starch and cause intestinal irritation. Wheat which has been heated or become mouldy or which has germinated too early gives to the bread a close, mouse-like smell and a sharp taste and a greenish hue in spots. Such wheat in bulk does not slip cleanly through the fingers, nor can the hand and forearm be forced through it. Bread baked from it is difficult of digestion and causes flatulence. Spoiled wheat is poor in gluten and no amount of treatment or preparation or admixture with other grains can redeem the lost food value. Further fermentation may also result in the production of butyric or propionic acids. The custom of adding alum and copper to bread made from spoiled wheat to improve its appearance is well known. Alum bread resembles well-raised bread and hence is a dangerous fraud. Copper sulphate and also borax are used in bleaching, and while white bread may be innutritious and dangerous to health it may also happen that ill-looking bread is harmless and nutritious. Rye bread is not only irritating in itself, but rye is much less resistant than wheat to the activities of vegetable parasites. Black mildew is often found on the stalks and ears and the glumes may be covered with rust. In wet years rye is mouldy. All these affections, however, are insignificant in comparison with the ergot of rye. When there is a shortage of labor the ergot is not carefully separated from the rye, but the contamination is readily apparent in the flour and bread. During the present war ergotism has occurred to some extent in the Eastern battle zone.

Therapeutic Hints.

Hepatic Colic.—As the first measure for relief of the agonizing pain in this condition Whitla gives a hypodermic injection of morphine, $\frac{1}{4}$ to $\frac{1}{3}$ grain, combined with atropine. Chloroform affords complete relief and allows the passage of the stone through the orifice of Vater, due to the relaxation of the muscles. In mild attacks a large hot poultice or hot pack or stupe may be placed over the liver, but a bath in hot water is even better—105° to 110° F.—together with copious draughts of hot water in which bicarbonate of sodium, 60 grains, and sodium salicylate, 20 grains, have been added to each pint.

When attacks are to be expected the following mixture may be kept on hand and administered as soon as the attack begins:

R	Liquor. morphinæ hyd.....	5iv
	Tinct. cannab. ind.....	5ij
	Olei. menthæ pip.....	5ij
	Spt. æther. sulph.....	5iv
	Spt. chloroformi	5vj
	Spt. æther. nit.....ad.	5iij

M. Ft. Mist. Sig.—A teaspoonful with a tablespoonful of whiskey in a wineglassful of water when the pain comes on. To be repeated in 30 minutes if the pain continues and every 2 hours thereafter until relief is obtained.

Whitla also suggests olive oil as a measure for relief during the attack. It may be given in doses of 5 or 6 ounces, combined with a tablespoonful of whiskey or brandy, and 5 drops of oil of peppermint. Fifteen ounces of the warm oil may also be injected into the rectum. In the after-treatment olive oil may be given in 4 to 8-ounce doses on an empty stomach.—*Dictionary of Treatment.*

For Relief of Anorectal Varices in Pregnancy.—F. M. Suarez advises the following prophylactic and curative measures: For prophylaxis, the taking of olive oil before each meal, and the use of medicated toilet paper following defecation and gentle washing of the parts with warm water and absorbent cotton. If prolapse of the hemorrhoidal masses occurs after defecation boric acid or carbolic acid solution should be employed in the after-washing and the masses reduced with the aid of sterile gauze, then the patient should assume the left lateral position on the bed for twenty minutes. Masses which are not reducible must be treated by rest in bed and the application of very hot fomentations of thymol, one in 1,000 boric acid 2 per cent., or formol one in 1,000, followed by the following ointment if pain persists:

R	Zinci oxidi	2.0
	Adrenalin, 1 in 1,000.....	1.0
	Orthoform	1.0
	Stovaine	1.0
	Petrolati	30.0

Injection of four or five minims of a 1 per cent. solution of phenol in glycerin into the varices will produce an astringent effect, while severe cases may require dilatation of the sphincter to relieve strangulation. The patient should not indulge in long walks, and when sitting the weight of the body should be placed alternately on each buttock rather than on both at the same time.—*Revista de Medicina y Cirugia Practicas.*

WOUNDS OF THE THORAX IN WAR

By JOSEPH RILUS EASTMAN, M.D.,
INDIANAPOLIS.

IN non-penetrating wounds of the chest wall we have to consider: (a) Wounds involving skin only; (b) Wounds involving deeper soft structures of chest wall.

(a) Wounds involving the superficial chest coverings must not be regarded as trivial unless it can be proven that there is no associated injury of deep structures. Large blunt vulnerating objects such as boulders may so strike the chest wall as to cause little external damage and yet cause fracture of bones or rupture of great vessels or injury of the heart itself.

Treatment.—Skin wounds are to be cleansed and covered with dry or moist antiseptic dressings, antiseptis, as distinguished from asepsis, being practised in every instance in which there is the slightest possibility of infection having entered the wound. If error is made it should be made upon the side of safety. Simple contusions of the chest wall require no active treatment unless shock is present which is dealt with promptly by recumbent posture, external heat, brandy or whiskey internally, saline-proctoclysis and salt solution subcutaneously or intravenously or, when indicated and possible, blood transfusion.

(b) Wounds involving the deeper structures of the chest wall are not often fatal but are nearly always infected and may be serious, for example, when there is injury of the internal mammary artery. Wounds of this vessel have often caused fatal hemorrhage, whereas wounds of the intercostal vessels are only rarely serious. The internal mammary artery accompanied by the vein passes downward from the third intercostal space one cm. lateralwards from the edge of the sternum. It lies upon the inner surface of the chest wall behind the costal cartilages and in front of the pleura and the triangularis sterni muscle.

Symptomatology of injury of the internal mammary artery in non-penetrating chest wounds.—(1) General signs and symptoms of hemorrhage; (2) Severe hemorrhage from wound traversing course of artery; (3) Difficulty and pain in swallowing; (4) Extra pleural hematoma evidenced by flat percussion note; (5) Hematemesis absent.

Treatment.—Enlarge the wound by an incision parallel to the costal cartilages and ligate both ends of the vessel or vessels. If the ends can not be found after thorough search in the enlarged wound, make other transverse incisions in the intercostal

spaces above and below to ligate both ends. Such extra transverse incisions should not be made unless quite necessary. If incision in the course of the internal mammary artery is made the large infracostal branches may be divided if care is not used. In injuries of the infracostals (these are the branches of the intercostal which course along the lower border of each rib) it is usually necessary to make a partial subperiosteal resection of the cartilage or rib to reach the vessels as they lie behind the lower costal border. To reach the infracostals the periosteum of the lower border of the rib may be freed by an incision along the lower posterior border with an elevator or rasparatorium and the vessel ligated as it lies in the freed periosteum.

In hemorrhage from an intercostal the bleeding in most cases can be controlled by Desault's method in which the center of a square of gauze is pressed into the wound with the finger. After withdrawal of the finger the pocket formed by the square of gauze is packed with a gauze wick.

Deep non-penetrating wounds of the chest are usually infected and heal slowly because of the respiratory movements.

Treatment is that of simple gunshot wounds, consisting in removal of foreign bodies and antiseptis, as with Dakin's solution, to which is added strapping of the chest with adhesive plaster to provide immobilization.

The treatment is conservative except in grenade or shrapnel wounds with extensive laceration, when careful excision of all crushed tissue should be made simultaneously with the removal of the metal fragments. Open treatment of the wound is preferable here as elsewhere. Foreign body reaction caused by gauze and dressings should be kept at the irreducible minimum. The wound may be protected from painful contact with clothing by strapping a wire cage or cardboard frame over it with adhesive plaster.

Penetrating wounds of the chest wall:—(a) Associated with fracture of bone; (b) Involving the pleural cavity; (c) Involving the lung; (d) Involving other organs of the chest.

(a) Wounds with fracture. Symptoms.—There may be no abnormal mobility, no pain, and no crepitus, therefore one must use care not to overlook the fracture. Usually there are present: (1) Sharply localized tenderness, (2) Pain with respiratory movements, (3) Emphysema of skin, (4) Crepitation, (5) Abnormal mobility.

The prognosis is good, four weeks sufficing usually for consolidation. False joint rarely results.

Treatment.—Partial fractures of the rib receive ambulant treatment unless associated, as indeed they often are in war, with hemothorax or pneumo-

thorax. Complete fractures should be treated in the recumbent posture. Morphine may be given for painful coughing. Loose spicula of bone should be removed. Splinting is best accomplished by adhesive plaster, applied as weather boards are laid on. Heavier and more complex splints and casts are as a rule ill advised in rib fracture. If the emphysema is extensive it may be reduced by introducing one or more aspirating needles into the emphysematous area and allowing them to remain for several hours. In threatening cases of emphysema an incision down to the fractured rib should be made under local anesthesia to allow escape of the air. A gauze wick is inserted to keep the wound open. Gunshot fracture of the sternum may be followed by mediastinal phlegmon.

In penetrating injuries of the chest involving the pleura to the exclusion of the lung the principal symptoms are those of hemothorax or pneumothorax, or both, with dyspnea but without hemoptysis.

The common complications are pleuritis and empyema.

The symptoms in chest injuries involving the lung are those of shock, hemothorax and pneumothorax with cutaneous emphysema, hemoptysis, pain, cough, and dyspnea.

Lejars says of the patient with serious hemorrhage of the pleura and lung, "He is pale, in great anxiety, the extremities are cold, the pulse scarcely perceptible, the breathing rapid and labored, the involved side of the chest promptly shows increase in size, the percussion dullness ascends, respiration sounds disappear, the heart is displaced, and often the threatening symptoms of syncope present themselves. Usually the patient coughs up blood, and with inspiration as well as with expiration blood mixed with air bubbles from the wound."

Shock is present especially in cases associated with pronounced injury to the chest wall. Pain is marked in cases complicated by fracture of the ribs and laceration of the pleura.

Hemoptysis is present in about 75 per cent of cases (Stevenson quoted by LaGarde). As a rule it ceases in a few days and rarely requires treatment. The cough is in some instances slight and of short duration. Many cases of penetrating gunshot injury of the chest die soon after the trauma from the loss of blood and the blocking of respiration. If the large vessels of the lung hilus are injured great hemorrhage into the pleural space results. Death on the field from this cause is often observed. Death sometimes occurs several hours after the receipt of injury as the result of hemorrhage from vessels of medium calibre or from large vessels bleeding intermittently. Others die later as the result of high tension pneumothorax combined with hemothorax, or, in a still later stage, from infection of the clot.

The air which enters the pleural space except in open pneumothorax is as a rule absorbed within a few days. Occasionally the wound acts like a valve permitting ingress but little or no egress of air. This leads to high tension pneumothorax. The subcutaneous emphysema is likewise of short duration and without significance in most instances.

Treatment of penetrating chest wounds.—The primary treatment consists of control of external bleeding, cleansing of the external wound, application of a sterile or antiseptic dressing, rest with

the chest elevated, heat, and morphine. In cases manifesting shock proctoclysis and subcutaneous or intravenous injections of physiological saline solution are to be used promptly.

Primary operative intervention for control of bleeding of the pulmonary vessels has in the main given way to conservative or expectant treatment, although Delorme, Robert, Michaux and others have made thoracotomies, turning back large flaps of chest wall to reach bleeding vessels of the lung, transfixing the parenchyma, and ligating the vessels with silk and in one instance packing the region of the lung hilus with gauze.

Landois (Brun's War Volume II, No. 9), while admitting the important role of conservatism in clean-cut bullet wounds of the chest, relying in such cases on primary expectant treatment with subsequent puncture for removal of blood or rib resection for drainage of empyema, if present, advocates active primary interference in cases of open pneumothorax with large wounds as caused, for example, by close range grenade explosions. He reports two cases of the latter kind successfully treated by primary operations in which he closed extensive bleeding lacerations of the lung with silk suture. In several instances the injured lung was drawn into the chest wall wound and sutured to the chest wall muscles with button sutures providing air tight closure of the lung wound.

Landois, Burkhardt, and Sauerbruch (Brun, *loc. cit.*) believes that in chest wounds with open pneumothorax and lung laceration the conservative standpoint should be abandoned and primary operation undertaken, provided that, in the field, time and other circumstances permit. They class such operations along with trephining and amputating as life saving.

They call attention to the small danger of infection of the lung at the site of suture and indeed all war surgeons have been impressed by the remarkable resistance of lung tissue against infection. In a large material the writer observed no instances of infection of a bullet canal in the lung parenchyma. Results, however, in the main have not justified aggressive primary interference. In the war, even more than in peace, the preponderance of opinion favors conservatism. Nearly all gunshot injuries of the lung with narrow canals recover after a few weeks with no more serious complication than a moderate hemothorax. Naturally, conservative treatment does not exclude aspiration of the fluid in hemothorax nor the air in high tension pneumothorax, the removal of fluid and air nearly always being followed by prompt relief.

It is well known the fresh cases of penetrating chest wound do not bear long transport journeys favorably. The danger of recurring hemorrhages, for example, justifies deliberation in sending them back and when sent they should be transported under the best possible conditions, the morphine syringe always being at hand.

Common complications of penetrating chest wounds are: (1) Hemothorax, (2) Pneumothorax, (3) Empyema, (4) Lung hernia, (5) Pleuritis, (6) Pneumonia, (7) Bronchitis, (8) Lung abscess and gangrene, (9) Fracture of ribs clavicle or scapula.

Hemothorax is a common complication of pene-

trating chest wounds and may be serious and persistent. It may be sterile or septic.

Symptomatology of sterile hemothorax:—(1) Decreased respiratory movement on involved side. (2) Diaphragm in a state of atonic relaxation, therefore the area of stomach resonance is high on the involved side. (3) Percussion note is dull over involved area. (4) Heart is displaced by effusion on left side. (5) Skoda's resonance above area of effusion. (6) Tactile fremitus is reduced over involved area. (7) Respiratory sounds are weak in the emphysematous area above effusion and tubular over the dull area. (8) Buzzing vocal resonance over the emphysematous area above the effusion; diminished vocal resonance over the effusion. (9) Dyspnea marked from the beginning. (10) Hemoptysis. (11) Fear. Usually not high, occasionally showing accessions due to fresh hemorrhages. (12) Slight icterus from absorption of blood.

According to Wullstein and Wilms, the blood in hemothorax for the most part remains fluid, clotting only where the epithelial covering of the pleura has been destroyed. Therefore, in their experience, the blood removed by the exploring needle from the pleural space in hemothorax, even weeks past trauma, is usually fluid. Bradford and Elliott, however, believe that clotting always takes place and very early through the action of the ferment liberated at the surface of the wounded tissues. Clotting, however, may be interfered with by the churning movement of respiration so that the fibrin is whipped out in layers over the pleural surfaces while the serum retains most of the corpuscles in suspension. The resorption of the blood progresses much more slowly than resorption of air, six to ten weeks being required for the former.

Differential diagnosis of hemothorax.—(1) Pneumonia: Fever high, leucocytosis, crepitations are present and there is no displacement of the heart as in hemothorax. The x-ray shows the shadow of the clot in the latter. (2) Pyothorax: General symptoms of infection are present. The exploring needle is decisive. (3) Pneumothorax: The x-ray and exploring needle are decisive. (4) Massive collapse of lung associated with abdominal injuries. The deciding criterion here according to Bradford and Elliott (*British Journal of Surgery*, October, 1915) is that in the massive collapse there is no displacement of the heart.

Treatment of sterile hemothorax.—The first step in treatment in the field consists in the application of a sterile dressing to the wound, strapping of the chest and administration of morphine. The patient should be kept in the recumbent position and propped up on a back rest for comfort. "Quies non movere" is a trusted maxim for observance in the first period after receipt of the injury. Transport should be delayed until the danger of fresh hemorrhage has passed. Later the principal indication of treatment consists in rest in bed. In the Austrian hospitals rest, as emphasized by von Eiselsberg, has been the watchword in the treatment of sterile hemothorax. Fortunately, in most cases the hemothorax is slight. It is a good rule to delay aspiration or other surgical operations long enough to permit healing of the wounded blood vessels, the removal of the blood being apt to dislodge coagula and cause recurrence of hemorrhage. If the accu-

mulation of blood is extensive, for example, rising half way up the scapula or higher, embarrassing the heart or respiratory movements, then aspiration may be performed. Aspiration prevents permanent contraction of the lung. Aspiration of a part promotes resorption of the remaining blood. It also enables one to make bacteriological examinations to the end that infection may be detected early. A good plan, therefore, is to remove only a part of the blood by aspiration at any one operation, repeating a second or third time, if necessary. Before aspirating, morphine should be administered to control the cough.

In sensitive patients a local anesthetic, preferably novocain, may be required. This, however, is rarely necessary. Removal of the blood by aspiration tends to minimize fibrin deposition and retraction of the lung. The great importance of rest and conservatism in hemothorax is generally admitted, but in this war the prompt removal of blood which resists absorption has been established as conservative practice.

After the danger of bleeding has passed hemothorax patients should be gotten out of bed and into the fresh air and sunshine. Absorption may be promoted by electric light baths and breathing exercises. Artificial pneumothorax produced by nitrogen injections into the pleural cavity are recommended in obstinate cases to loosen adhesions and promote absorption.

Septic Hemothorax.—H. Henry, who studied bacteriologically the cases of Bradford and Elliott (*vide supra*) found the pneumococcus, micrococcus, and tetragenus, the *B. influenzae*, the staphylococcus, streptococcus, and anaërobic bacilli of fecal origin in infected hemothorax. Some of these are denizens of the lung, others were introduced with the missile. They found that jagged shell wounds are more likely to be septic than are bullet wounds.

The clinical features indicating infection of hemothorax are: (1) Rise of temperature, (2) Increase in pulse rate, (3) Pain and tenderness, (4) Insomnia and delirium.

The physical signs do not differ materially from those of sterile hemothorax. The infection is first recognized by the rise of temperature. In uninfected bullet wounds of the chest the temperature curve rises slightly for one or two days and returns to normal. After six or seven days in sterile cases comes the resorption fever with an elevation of one or two degrees above normal. If it does return to normal there may be a circumscribed pneumonic process present in the neighborhood of the bullet canal, but much more probably an infection of the hemothorax of pulmonary origin has begun. Infection should be suspected in all cases which are not progressing favorably after the fourth day.

Treatment of septic hemothorax consists chiefly in thoracotomy with removal of the infected fluid and subsequent irrigation.

Empyema.—The diagnosis of empyema following chest injury, either as a result of primary infection in the depth of the wound or in the form of supuration of a hemothorax weeks after injury, is usually easily made. The blood count, temperature curve, and physical signs will give sufficient criteria for diagnosis in frank cases. It should be noted, however, that empyema developing in an encap-

sulated hemothorax, for example, in the upper chest masked by fractured ribs or hidden behind the scapula, may elude diagnosis and lead to general pyemic infection.

Symptoms: (1) Flat percussion note (usually in lower posterior chest area, not changing as patients move about). (2) Decreased fremitus. (3) Sharply outlined shadow on x-ray examination. (4) Patient lies on involved side. (5) Intercostal spaces obliterated. (6) Increased semicircumference. (7) Higher temperature than is present in serous exudates. (8) Hematologic signs of suppuration.

Since it is not easy to determine by physical examination the character of fluid in the chest it is obviously essential in any suspicious case to make an exploratory needle puncture and bacteriologic examination.

When empyema is present thoractomy with rib resection is required for drainage. If the original wound is on the dorsum and low, it may be used in making the wide opening of the pleura, which is required. It should, however, not be used for the rib resection unless its position is favorable for drainage.

Lung Hernia.—Lung tissue lying loosely in the wound is of normal color, smooth, and crepitating. When strangulated, it rapidly becomes dark blue or black in color and the crepitation disappears.

Treatment.—If the hernia is fresh it should be reduced by pressure after disinfection of the external wound. In the early stages pressure empties the extruded lung of air, its bulk becomes smaller, and reposition is easy. Adhesions which form at the periphery of the wound between the lung and the chest wall are to be broken up by gentle manipulation. If one or more ribs offer resistance to reposition they should be resected. The sudden entrance of air into the pleural space during reposition should be prevented by the use of gauze compresses, the gauze compresses serving later to retain the lung in normal position during closure of the wound in the chest wall. If the lung hernia is several hours old and the extruded lung tissue is collapsed or gangrenous it may be abscised by ligating it en masse with silk, then dividing distal to the ligature with the actual cautery.

Concerning *pleuritis, pneumonia, and bronchitis*, it should be noted that they appear frequently after deep chest injury. The pneumonia may appear in the injured lung tissue or quite remote therefrom. Not rarely the sound side is the seat of bronchitis, and pleuritis is a quite common accompaniment or sequel of hemothorax.

Lung abscess and gangrene are rare in gunshot chest wounds. The former is usually associated with the presence of an infected foreign body as a fragment of uniform. Lodged bullets may be coughed up as the result of the communication of an abscess with one of the large air passages.

Injuries of the Heart.—Extensive lacerations of the heart may occur as the result of the explosive effect of a missile striking the liquid cardiac contents. The heart may also be injured by bullets which drive the pericardium against the heart without perforation of either. Immediate death in heart wounds occurs from hemorrhage or from reflex paralysis due to injury to the bundles of His.

Death may occur later from slow but continuous bleeding, usually into the pleural space. The extravenous pressure of the clot itself may fatally embarrass the heart's action.

Symptoms: (1) Pallor. (2) Small irregular pulse. (3) Dyspnea. (4) Cold perspiration. (5) Subnormal temperature. (6) Pain in the region of heart, extending to left shoulder and upper abdomen. (7) Dilatation of veins of neck. (8) Increased area of cardiac dullness. (9) Increased heart shadow on x-ray examination. (10) Subdued heart sounds and rustling sound of air entering pericardium.

The position and direction of the wound canal is obviously of importance in diagnosis.

Treatment.—Exposure of the heart is best accomplished by enlarging the gunshot or stab wound of the chest wall by incision forward and backward in an intercostal space. Forceful separation of the ribs may allow of convenient access, if not a rib or ribs should be resected. The pericardium is then incised, the heart drawn forward, and the wound closed with deep sutures of fine silk. A blunt round needle should be used. Rehn advises compression of the veins entering the right auricle to control hemorrhage during operation.

Prognosis of Immediate Operation in Heart Wounds.—Hesse (quoted in Wilms' Textbook of Surgery, Vol. I, p. 516) reviewing this subject reports 70 recoveries in 160 operations for stab wound of the heart and 12 recoveries in 27 gunshot wounds treated by immediate operation. He believes that one can count on about 45 per cent. of recoveries in heart wounds. The shorter the time between injury and operation the better the prognosis. Hesse says that in operations made during the first four hours the mortality should be no higher than 25 per cent.

Injuries of the Pericardium.—Wounds of the pericardium cause hemorrhage with accumulation of blood in the pericardial sac, causing pressure upon the heart and symptoms very like those of injury of the heart itself. Treatment consists in removal of the blood and ligation of the bleeding vessels. In cases seen several days after injury the blood may be removed by paracentesis. Pus in the pericardial sac demands ample drainage.

Wounds of the Large Vessels and Thoracic Duct.—Injuries of the large vessels of the chest are practically always immediately fatal. Occasionally the formation of a traumatic aneurism at the site of injury to the vessel may postpone the fatal termination. The comparative infrequency of injury of the large trunks has been explained by the assumption that the loose tissue of the mediastinum allows the great vessels to be pushed aside by bullets of low velocity. Injury of the thoracic duct often leads to fistula with chyloorrhea or chylothorax. The chylous fistula usually heals.

Wounds of the Diaphragm.—These are principally of interest in connection with associated injuries of other organs. Hernia diaphragmatica in which abdominal viscera, as the stomach, are extruded from the abdomen upward through a wound of the diaphragm is rare. In some instances the abdominal organs have been replaced through a chest incision with rib resection and the wound of the diaphragm closed by suture. Wounds of the diaphragm are reached more easily from above.

Concussion, Compression, and Contusion of the Chest.—A blow upon the epigastrium may produce a reflex arrest of the heart's action. Such arrest with symptoms of shock may be caused by suddenly increased air pressure due to the bursting of a grenade at some distance from the trunk.

Violent compression of the thorax may produce hemorrhages or petechiæ from the small veins of the head and neck with ecchymoses into the conjunctiva and the ear drum. Rupture of the lung may occur without demonstrable injury of the chest wall. Reflex closure of the glottis locking the air in the lung during the compression of the elastic chest is the determining factor in some instances. The heart and pericardium may also be injured by contusion of the chest without injury of the chest wall. Contusion of the chest is not uncommon on the mountainous frontiers, such as the Italian, where boulder warfare is practised.

Lodged Bullets in the Chest.—Grenade fragments, shrapnel balls, and rifle projectiles of low velocity frequently find lodgment in the chest. They may be retained in the chest wall, the pleural space, and the lung, or may lodge in the spinal column. No operative attempt should be made to remove foreign bodies in the chest excepting superficial ones unless it can be proven that untoward symptoms are caused by their presence. This is unusual. The ability of the lung tissue to tolerate foreign bodies and to resist infection should be borne in mind. Operation for removing bullets in the pleural cavity may be undertaken if pain and other symptoms persist. Careful *x-ray* examination is, of course, an indispensable preliminary step. Plates should be made in at least two directions and the operation should be done on the *x-ray* table. An assistant wearing the *x-ray* or fluoroscopic spectacles of Holz knecht or the monocle fluoroscope may, by pointing with a heavy probe, guide the operator to the foreign body. The cryptoscope of Bettman, a small fluoroscope which can be opened by a spring to permit operative movements under direct ocular guidance and closed at will to permit *x-ray* inspection, is of great value here as in the removal of all foreign bodies. It is strapped to the head of the operator or an assistant. Such a device is superior in usefulness to plates because with it one may follow all movements of the foreign body due to change of muscle, tone, respiration, etc. An old-fashioned small fluoroscope with a handle may be used by an assistant who points with a heavy probe to guide the movements of the operator.

331 NORTH DELAWARE STREET.

REPORT ON 10,000 CASES FROM THE CLEARING HOUSE FOR MENTAL DEFECTIVES.

BY M. G. SCHLAPP, M.D.,
NEW YORK.

PROFESSOR OF NEUROPATHOLOGY, NEW YORK POST-GRADUATE
HOSPITAL AND MEDICAL SCHOOL,

AND

ALICE E. PAULSEN, M.A.,
NEW YORK.

PSYCHOLOGIST, CLEARING HOUSE FOR MENTAL DEFECTIVES.

I.—Few problems of such grave importance to humanity are understood so little, not only by the lay public but by the medical profession, as that of the mentally defective. Though it is

fundamentally a medical problem, it is only within recent years that physicians have seriously considered it, and even at the present time the subject attracts comparatively little attention in the medical school.

The increasing public interest in the care of the mentally defective seems to be a culmination of the growing feeling among social workers of all types, as well as among physicians who have become interested in the field, that some underlying cause must be found for the failure of so many, both adult and juvenile, to hold the place which should be normally theirs among their companions.

There have recently been proposals from various sources that cities, states or private institutions establish clearing houses for mental defectives, and the proposals have met with varied response. How great the need for such institutions has been proved beyond a doubt by the success and usefulness of the original Clearing House for Mental Defectives, which was established by Dr. Schlapp, in 1911, at the Post-Graduate Hospital in New York City, and which is still carrying on its work there. So far as is known to its sponsors, this was the first institution of its kind ever proposed and actually established.

In the course of his work at the Presbyterian Hospital, some years ago, Dr. Schlapp was greatly impressed with the need for more adequate methods of dealing with the numerous defectives brought to the hospital clinics for treatment of various conditions, and it was then that he conceived the plan which he later put into practice.

The institution founded in 1911, formulated as its aim the detention, scientific diagnosis, registration and research into mental deficiency, and recommended that all persons found to be socially unfit, actually or potentially, possibly as a result of mental defect, should be referred to the Clearing House by the agent of the department or society which discovers them, and that at the Clearing House they should be subject to the following procedure: (1) Complete registration and identification of the person by means of photographs and by mental and physical measurements, combined with a complete history of the case and all relative facts obtainable; (2) diagnosis; (3) recommendations for care, treatment, and training proper to each case; (4) follow-up work.

In the beginning the Clearing House received its patients from chance applicants at the hospital and from miscellaneous social workers who knew of its existence.

Previous to this time there had been no definite systematic examination of applicants before admission to the Randall's Island Schools for the Feeble-minded. The statement of any private practitioner, whether he was known to be a competent neurologist or not, had been accepted as sufficient authority for the condemnation of a patient to institutional life indefinitely, or for as long a period as his guardians might choose.

Also, the judges of the Children's Court had long felt that many persons came before them who were charged with offenses which seemed to be due to mental or moral defects rather than to causes correctible by the penalties usually imposed. The Society for the Prevention of Cruelty to Children

first instigated the examination of these children by Dr. Schlapp.

In 1913, Commissioner Drummond of the Department of Public Charities recognized the Clearing House as the official examining place for admission to Randall's Island. The sum of \$34,000 was requested; \$3,400 was apportioned by the Board of Estimate to be applied to the work.

The Clearing House, on its new basis, now examined every case brought to it by the Department of Public Charities, and as many as possible of defectives who applied for admission to or care by city institutions. It examined all children sent to it by the Children's Court or the Society for the Prevention of Cruelty to Children. Besides these, it was open to all settlements, schools, churches, missions, hospitals, private and public charities, physicians, social workers of various kinds, and in fact to any one who in any way came into contact with a suitable case for which expert attention was desired, and not obtainable elsewhere.

Since the summer of 1915 the official relationship between the Department of Public Charities and the Clearing House has been severed.

After a fight of three years the State Legislature of 1913 passed a bill which Mr. Jonah Goldstein and Dr. Schlapp had had introduced, providing for proper examination of children passing through the courts, and in January, 1917, the courts, basing their authority on this law, established a separate clinic for their own cases. The original Clearing House, however, continues its work just as it always did, receiving patients from any agency which may find occasion to use it. On the average, about 1,500 new cases are seen every year. In the last year 5,471 patients, both new and old, have visited the clinic for help.

The patients are admitted through the dispensary, as is done with all hospital clinics, this particular one being known by its original name, "The Clearing House for Mental Defectives." How greatly the work has been facilitated by this intimate connection with a thoroughly equipped hospital is beyond estimation, and the debt which the Clearing House owes to the Post-Graduate Hospital cannot be readily determined.

Through this close connection patients can readily be transferred, for instance, to the eye or ear clinic for treatment of defects of the special senses; Wassermann and other tests may be given, x-ray examinations may be made, and any physical disability may be properly treated in conjunction with the examination given at the Clearing House. There are even certain hospital beds at the disposal of the director should he desire to keep cases under care and observation at the hospital.

The Clearing House has now examined over 10,000 cases. In subsequent pages will be found a general survey of the work, with tables and charts showing the results of a review of its first 10,000 records. An analysis of the following data will be attempted in subsequent papers.

II.—Outline of History Found in Clearing House Records.

1. Case number
2. Date of application
3. Name of applicant
4. Address of applicant

5. By whom was the applicant referred to the Clearing House, and why?
6. What is the applicant's religion?
7. Sex of applicant?
8. Civil status of applicant?
 - (a) Citizen
 - (b) Non-citizen
 - (c) Non-resident
9. School, if any, which the applicant attends. What grade?
10. Occupation of the patient
11. (a) Actual age. (b) Mental age as shown by tests.
12. Birthplace of

(a) Father	}	If foreign, how long in the U. S.?
(b) Mother		
(c) Patient		
13. To what race does the patient belong?
14. Family history
 - (a) Hereditary factors. Is there any history of psychopathic or neuropathic conditions, disturbances of the endocrine system, or any other deviations from the normal.
 - (1) Amentia
 - (2) Syphilis
 - (3) Insanity
 - (4) Tuberculosis
 - (5) Alcoholism
 - (6) Criminality
 - (7) Toxins
 - (8) Epilepsy
 - (b) Occupation of
 - (1) Father, before and after marriage
 - (2) Mother, before and after marriage
 - (c) Complete list of children in the family, including the patient; age of each.
 - (1) What is the stated mental condition of each?
 - (2) What was the mother's condition during gestation?
 - (3) If of foreign parentage, how long were the parents in the U. S. at the time of gestation of the patient?
 - (4) What conditions attended parturition, was it normal or abnormal?
 - (5) How long did lactation continue? Condition of the mother?
 - (6) If artificially fed, how?
15. Personal history
 - (a) Condition of mother during pregnancy, conditions attending parturition and lactation (obtained from section 14 c).
 - (b) Has the child ever sustained any trauma or injury?
 - (c) What diseases has the child had?
 - (d) Describe the child's environment and erudition. Habits.
16. Status Præsens
 - (a) General physical condition. Neurological examination
 - (b) Note any physical defects or abnormalities
17. Additional data, and various mental tests
18. Diagnosis.
19. Recommendations
20. Remarks

III.—Tables and Charts Presenting Data Obtained from an Examination of the First 10,000 Histories.

ment of those who, after careful investigation, are found to be mentally normal. Such negative findings are surely contributions as valuable both to the individual and to the society concerned with them, as is the other function of the Clearing House—that of detecting those who actually are feeble-minded.

It is also of primary importance that all cases, not placed in institutions, should be studied care-

CHART 2.—Ratio of American to foreign born parents having American born offspring in the clinic.

CHART 3.—Comparative number of males and females.

IV.—The Clearing House for Mental Defectives has initiated an important work. The intention of the director has been to have the Clearing House serve as an experiment for the city and the State. The care of the feeble-minded is not properly a local and assuredly not a private philanthropic matter. It is regarded as conservative to estimate the total number of aments in the State as 35,000, about one-half of them residents of Greater New York. The dangers to the community are great and manifold. Of course, it is impossible to even consider institutional care for all as a present remedy. Because of the inadequate accommodations, it is the more important that careful scientific diagnosis be made in all cases, precedent to commitment, in order that those who because of utter deficiency or malicious delinquency are a menace to society, may be given preference in our institutions, and also in order to avoid the still greater crime of commit-

CHART 4.—Numerical comparison of races represented by the Clearing House patients, cases 3,000 to 10,000: Anglo-Saxon, 325; Celtic, 789; Teutonic, 647; Latin, 915; Semitic, 2,198; Slavic, 237; Mongolian, 1; Negro, 118; doubtful, 1,880.

CHART 5—Sources and Disposition of Cases 1-7500

fully and, if possible, treated so as to fit them to adapt themselves to their environment, or that an available environment which is most suited to their

limited capacity for self-respect and self-support should be recommended for them.

In other words, where it is not feasible to segregate all who are feeble-minded, it is necessary to have such an agency as the Clearing House to select for institutional care those who form the greatest source of peril to the community, and to help the others to maintain as normal a social life as is within their capacity, adapting the form of such help to the particular needs of each individual and determining these by careful educational, psychological, medical, and psychiatric research.

At present the Clearing House, while unable to fulfill its ideals satisfactorily to itself, nevertheless is serving the community at large by doing as many things as its limited equipment will allow. In all essential points it is doing as well as is humanly possible under the existing circumstances.

CHART 6.—Curve showing distribution by ages for 100 cases. Note rise of curve, about adolescence, when instability is at its height. (See Table VI.)

To cover the needs of New York City, such an institution should be equipped with a competent paid staff, consisting of at least ten physicians, four psychologists, one chief examiner, ten stenographers, one filing clerk, one statistician, three trained nurses and social investigators. Only by enlarging the staff in this way can New York City properly cope with the insistent problem of the mentally defective. Only in this generous way can the many departments of government, and the auxiliary social agencies concerned, be assisted in their efforts to provide for those who, because of mental defect, have become a burden and a menace to society at large.

As has been stated, the care of the feeble-minded is not a local nor a private philanthropic matter. All efforts should and must be made a separate part of a coordinated, unified attack on the whole problem by the State authorities.

A chain of public psychopathic clinics should be established in the various populated centers of New York State and maintained as part of a State-wide program for detection, detention, examination, and study of the mental defectives in the community. In order to make the work more uniform and the results of greater social value, these clinics should be organized and directed by a State board, appointed by the Governor.

The members of this board, serving voluntarily and representing all the various professions interested in this problem, could do much, aside from their supervision of these clinics, to advance the cause of social prophylaxis in mental defect. The greatest barrier to the furtherance of this program has been the lack of cooperation on the part of the experts in the various fields of social effort, who come into most intimate contact with the feeble-minded, and should, therefore, work in the greatest harmony for their betterment.

Any spirit of jealousy, personal ambition, and petty partisanship must give way to the large and more truly social spirit of co-operative effort toward the one purpose that is common to all—the public provision for the feeble-minded, and the public prevention of feeble-mindedness.

FLAT FEET AND TWO OPINIONS.

BY DOUGLAS H. STEWART, M.D., F.A.C.S.

NEW YORK.

THIS may seem to be a paper dealing with a matter of little or no importance. It seemed so to the author; but men who are interested in the government services may have a very different estimate of it, may even have a contrary idea, and their opinions may turn rather toward a view that the simple expedients here mentioned may make available much man-power that is now "scrapped," even though money expenditure may not be lessened. For it must be well understood by this time that very many men, who are both willing and anxious to perform the necessary duties that are required in naval or military forces, are handicapped solely by flat feet and must be discarded, even though otherwise they are physically perfect. Therefore when one thinks it over it may be worth while to consider a method of treating those flat feet that may be employed by nurse or doctor and may be utilized when

no instrument at all is obtainable, not so much as a brace, or a pair of scissors, or even a pocket knife.

"Acquired flat foot" is the variety to which the present remarks apply, and this, roughly speaking, presents the symptoms of too much pronation and too little supination. The osseous process that prevents supination is the sustentaculum tali; why not attempt to roll the os calcis outward in an endeavor to obtain too much supination and too little pronation? As to the question of power, why not use the whole weight of the patient's body as the upsetting force? As for the employment of the principle of the wedge, a rock may be rent, a locomotive lifted, or the reinforced chilled steel doors of a bank vault may be burst asunder by such an instrument.

Attempts have been made, with more or less success, to accomplish the aforesaid results by building up the inner side of the heel of the shoe; but there is too much lost motion, or slip and slide, between foot and shoe, even if so much as the discussion of any special shoe were not here prohibited by the very proviso already made: that *no* instrument whatever is to be considered available. It may be said, however, that many such special shoes have been turned from previous failures to successes by the use of the means shortly to be described when those means have been employed in addition to the shoe.

Let anyone take an ordinary blotter and fold it end to end and crease it firmly in order that it may stay in position. Let him take a second piece of blotting paper, treat it the same way and lay one folded paper upon the other so that the upper folded edge shall not approach the lower closer than one-quarter of an inch in distance. Let the figure thus represented stand for a block or wedge that shall make the os calcis fall down stairs sideways, or rotate outward, whenever the patient is upon his feet. As a matter of fact the nurses adopt a much simpler plan and make the staircase with a single flip of the hand. Since the principle is the important matter, the description here given will work for clearness of understanding. Thickness of material or height of stair does make a difference in clinical result, but that will be easily adjusted to produce the effect desired and the possibility of getting the shoe on will put an impassable barrier to any excessive height. The idea is to produce something like this:

Then if *B A* represented one-quarter of an inch and *A* were placed $\frac{1}{8}$ inch inside of the middle line of the plantar surface of the os calcis, *C* and *D* could be turned over to cover the inner surface of the astragalus, os calcis, scaphoid, etc.

If one had a vaseline bottle and imagined that to be an os calcis of the right foot, and if one put a narrow strip of adhesive plaster across the bottom of the bottle to represent the posterior view of a perpendicular to the bearing surface of the right os calcis, surely he could put the step or block that has been described under that bottle, in such a way as to understand how the weight of the body will make the os calcis fall or rotate outward.

A regular triangular wedge has been tried, but the pressure of the foot itself bites, as it were, upon

this stair, and slipping is not a factor to be considered. In fact, a series of stairs could be constructed to cross the whole foot and then any lateral pressure would be negligible.

In short, one is to make the stair-wedge of two gauze wipes and bandage them in position with an ordinary roller. If such a roller is carried forward upon the phalanges of the toes, not only will the good influences of the expedient be brought to naught, but a pointed foot or some degree of hallux valgus may be brought about.

Two Opinions.—The first opinion is set forth in the following letter from Dr. C. A. Frink of New York:

Mr. Dear Dr. Stewart:—Thanks for your very interesting notes. I think this is just the time and place for you to write up your care of painful feet with whys and wherefors. I have put down a few points that you might use with your own, as the result of our trying it on our station. Surgeon T. A. Lynch, U. S. N., in charge of the Federal Rendezvous Training Station, has given his assistants permission to try the gauze pad treatment of Stewart for flat or painful feet.

Observations of Assistant Surgeon C. A. Frink on over 100 cases:

1. Men coming from private life find that the drills and work cause many of them to have painful feet. If they are taken at once, taught foot exercises, together with the use of pads, we find they can continue with their work and in about two weeks they are well.

2. These men are kept useful and are not given medical discharge, therefore a saving of manpower.

3. Saving of adhesive plaster, which is scarce and expensive.

4. No abrasions of the skin as in the use of the plaster.

5. Men can remove them every day to bathe the feet.

6. Most men can quickly learn to apply them on their own feet.

7. Very simple method to teach hospital corps men, showing them the skeleton bones of the foot; in a few minutes they grasp the reason why.

8. The pads turn the foot just enough without the pain of other methods.

9. The men do not depend upon them as on plates, for as they grow stronger they leave them off, continuing to use the foot exercises. We find from two to three weeks is enough, at times three to four days.

C. A. FRINK.

The second opinion is that of a well-known pathologist, but he refuses to allow the publication of his letter. "However, its statements may be incorporated if the present writer assumes all responsibility." He does. "Your idea that the ultimate analysis of the mechanics of the ground—os calcis-contact—will show but a line rather than a surface, so that it may be compared with the contact of a bottle with the top of your desk, or with a carwheel with its rail, is new to me; but that is not at all to be considered a proof of its novelty to others. It is reasoned out upon an anatomical basis and with due regard for the pathology of pes planus. After all, anatomy and pathology are the only worth while sciences that are comprised in the total which we

know by the name of medicine, consequently your gauze pads have a value. Since the procedure has been successfully tried upon many patients and by various doctors and nurses, I would recommend its further trial both upon anatomical and pathological grounds."

In conclusion, the patient may massage his own feet to great advantage, as he may also place the inner borders of the feet in contact and learn to practise standing upon the outer edges of the feet many times a day. Other expedients have been incorporated into standard text books and would be but "padding" here.

128 WEST EIGHTY-SIXTH STREET.

SYMPTOMATIC ATELECTASIS.

BY ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

PHYSICIANS unskilled in percussion associate impaired lung resonance with gross changes in the physical structure of the lungs, and fail to recognize changes in pitch before alterations in the quality of the percussion sound.

The writer's experience with physicians and students constrains him to conclude that errors are most frequent owing to the non-recognition of differences in the percussion note rather than inability to elicit them.

Instrumental is easier than finger percussion, although less reliable. In finger-finger percussion one can appreciate the resistance of tissues percussed (plessesthesia) and adapt the finger to irregularities of the superficies.

To thoroughly appreciate changes in resonance, light percussion is indicated, inasmuch as it is a

FIG. 1.—Pulmo-diagnostic reaction in congenital and acquired syphilis. The area of dullness measures approximately 4x4 cm. The location is defined with arms hanging. During percussion, the subject places his right hand on the left shoulder.

recognized law of sense perception that the less loud the initial sound the simpler it is to recognize its variations; and furthermore, a heavy blow dulls the sensibility of the finger tips.

Lung Reflexes of Abrams.—The lung reflexes' (contraction and dilatation) account for many modifications in lung resonance. If the lung reflex of contraction predominates, impaired resonance or dullness ensues, and if the lung reflex of dilatation predominates there is hyperresonance.

In England, Auld and Sir James Barr, and in Italy, Plessi, direct attention to the differentiation of atelectasis and consolidation of the lung; in atele-

lectasis, irritation of the skin contiguous to the affected area will convert the dullness into resonance, whereas if the dullness is due to a consolidation, elicitation of the lung reflex of dilatation will not influence the dullness.

FIG. 2.—Pulmo-diagnostic reaction in congenital syphilis. This area of impaired resonance is present in addition to the area demonstrable in Fig. 1.

In *x*-ray examinations of the lungs, an area of opacity due to atelectasis may be mistaken for consolidation; elicitation of the lung reflex of dilatation immediately clears the opacity in atelectasis, but has no influence on the shadow due to consolidation.

Cesare Minerbi of Ferrara, Italy, regards the absence of the lung reflex of dilatation posteriorly as one of the earliest and most trustworthy signs of pulmonary tuberculosis. This conclusion was based on a study of 300 cases and 14 autopsies.

Pulmonary Atelectasis.—The writer has frequently directed attention in the literature² to areas of lung collapse or atelectatic zones. Not infrequently the apex of the lung in its entirety may be atelectatic, and for this reason alone some individuals have been pronounced phthisical by physicians who fail to recognize lung atelectasis when detected by percussion or seen at an *x*-ray examination.

The writer has heretofore attributed these atelectatic areas to defective chest expansion, but he has adequate reason of late to ascribe their presence in part to another factor. A consideration of the latter factor is the essential object of this contribution.

Symptomatic Atelectasis.—Areas of impaired lung resonance are demonstrable over definite regions of the chest in various diseases not autochthonous to the lungs.

We shall be carried too far afield if consideration is given to more than one disease, and, as a paradigm, syphilis is selected.

It is a simple matter for the physician to demonstrate the following observation, but he must faithfully observe all the exactions necessary in executing the test. Select any individual who is known to have syphilis (congenital or acquired). Irrespective of treatment or duration of the disease, the sign is invariably present. Have the patient face the west. This refers to the geographical west, and the body of the patient must be parallel with the earth's axis.* Any deviation from this position will dissipate the area of impaired resonance.

*The patient stands on a plate of aluminum which is connected by a wire to a faucet, radiator, or gas or electric fixture. This grounding is absolutely necessary.

On percussion, one may detect an area of impaired resonance or dullness (Fig. 1) in the right interscapular region, which is most accentuated at the vertebral border of the scapula. If now the patient is turned either to the north or south, resonance will at once supplant dullness, and the latter reappears on resumption of the original position.

If the lung area in question is carefully auscultated, first in the modified position and then in the original position, bronchovesicular respiration and subcrepitant rales not detectable in the modified position will be heard in the original position. Allow at least one minute for the auscultatory changes to ensue.

The intensity of the dullness will be in direct proportion to the virulency of the disease.

In congenital syphilis, in addition to the area of dullness in the back (Fig. 1) there will be found an area of impaired resonance at the *manubrium sterni* and area contiguous to it (Fig. 2). The latter is likewise modified by the posture cited.

For more detailed information bearing on this and cognate subjects the reader is referred elsewhere.³

Explanatory.—The hypothesis of vitalism and the cell theory are anachronisms. The cell doctrine should be replaced by the electron theory.

Vital phenomena are dynamic, and the actions of organisms should be regarded as processes and not as structures.

The ultimate atomic divisibility of matter is represented by the electron and not the cell.

Every phenomenon in nature is dependent upon matter in motion or vibration, and energy is employed to designate the modes of motion in the universe.

The laws of physical science are universal, and apply equally to all things in nature.

The sun's radiations, with a short wave length are perceived by the eye as light; and the long waves, unperceived by the retina, and acting on the receptors of the skin, are called heat.

All matter responds to stimuli.

Color is determined entirely by the number of waves emitted by a luminous body in a second of time.

FIG. 3.—Area of pallor or flushing in a syphilitic, superinduced by grounding the vasodilator or vasoconstrictor center in the cord. The area represents a streak slightly above the lower border of the lobulus of the auricle.

When the optic nerve synchronously perceives a variety of colors there must be analyzers in the nervous system, or specific fibers in this nerve which are natural detectors always attuned to definite vibratory rates.

Symptoms are reflexes provoked by energy acting on definite centers.

When the fifth cervical segment of the cord (bronchoconstrictor center) is stimulated experimentally a contraction of the lungs ensues (total atelectasis).

Auld, in the *Lancet*, Oct. 7, 1903, in commenting on the lung reflexes of Abrams, observes that Roy and Brown, and later Dixon and Brodie, conclusively established the presence of bronchodilator and bronchoconstrictor fibers in the vagus. "But it undoubtedly stands to the credit of Abrams to have proved at least seven years since, by a simple clinical observation, that the vagus must contain bronchodilator as well as bronchoconstrictor fibers."

Disease, like color, or any other phenomenon, is a question of vibratory rate.

The *Spirocheta pallida*, or the toxinoses resulting therefrom, acting on definite fibers of the bronchoconstrictor nerves, will produce an area of dullness only in a definite lung region.

The localized hectic flush is an analogous condition; the toxins acting only on specific vasomotor fibers. The latter condition may be reproduced artificially, as the writer has shown elsewhere.⁴

In syphilis this specific action on definite vasomotor fibers may be noted as follows: The syphilitic stands on the ground plate, facing west. Fix an electrode connected with a conducting cord to the area between the third and fourth dorsal spines, and note a pallor within 10 seconds in the area designated in Fig. 3, when the end of the cord touches the ground plate. Flushing in the same area occurs when the electrode is fixed at the first dorsal spine. Observations must be made with subdued light. It appears to the writer—and in announcing this observation he seeks the cooperation of others before a final conclusion can be formulated—that in congenital syphilis, in addition to the area cited, there is an additional area of pallor or flushing limited to the antitragus.

The rationale of the foregoing maneuver may be found explained elsewhere.⁵

Relative to the influence of posture on the area of dullness, we must regard our earth as a gigantic magnet with poles. It is generally accepted—although the reverse may be true—that out of the earth's north magnetic pole in the Southern Hemisphere a stream of magnetic flux emerges which traverses the atmosphere until it attains the earth's south magnetic pole in the Northern Hemisphere.

All energy shows polarity. The syphilitic energy is neutral, and when the body of the syphilitic subject is turned either to the north or south the magnetic flux emerging from the north and re-entering at the south pole, or *vice versa*, suffices to account for postural polarity.

Addenda.—1. The dull lung area may be accentuated⁶ by firm pressure on the metasternum with the hand.

2. Modifications in the epicritic (hyperalgesia) and notably the protopathic sensibility (hypesthesia) strictly limited to the dull area may be demonstrated.

3. Paravertebral tenderness is demonstrable at the 5th and 6th cervical spines on the right side. Like the dullness, this is modified by posture although a longer interval of time is necessary.

4. With a stethoscope fixed in the center of the

dull area the inaudible strokes on the skin with a small camel's hair brush become audible when the limits of the dullness are attained.

The writer's galvanometric method of delimiting the dullness will be described in a later communication.

UTERINE FIBROID TUMORS.*

By FRANK D. REESE, M.D.,

CORTLAND, N. Y.,

SURGEON TO THE CORTLAND COUNTY HOSPITAL.

THE subject of fibroid tumors of the uterus is an old one which has been written upon from all angles. Yet it must remain a new subject for investigation until the cause or causes of this frequent trouble of women are found and a treatment is established which will remove or prevent these growths.

Mutilation of the body and unsexing do not furnish a pleasant thought for the average woman to contemplate. When one contends that every uterine tumor should be removed with the knife, unsexing many in the ordeal, it is time to stop and take an inventory of our knowledge on this subject of tumors and see if there is not something lacking in the understanding of the causes which produce these growths.

You might say to me, would you stop removing these tumors because we do not understand the etiology and let the patient drag out a miserable existence? I unhesitatingly answer no. But because we can remove these tumors with a relatively small mortality is no reason why all women who have fibroid tumors should undergo an operation which unsexes and leaves sequelæ which make life a miserable existence. There are hundreds of uterine fibroid tumors which are amenable to medical treatment and there are others which should be removed at once.

The cause of fibroma of the uterus is conceded to be some irritation, chronically constant, of the uterine tissues, with probably a heritage which lends a tendency to an easy formation of these neoplasms. This irritation—presumable but not known definitely—acts upon the glands of the mucosa, causing an hypertrophy which by contiguity of tissues extends into the endometrium. It is possible for me to believe that a segment of a hypertrophied gland may intrude itself into and between fibers of the muscle of the uterus and become occluded there, forming a nucleus for an intramural fibroid.

These theories are not fully established, only

*Read at a meeting of the Cortland County Medical Society, December 21, 1917.

in so far as treatment based upon this supposition has, in many cases, proved successful.

The irritation of sexual activity at the period of life in which the fibromata appear most frequently, prolonged virginity with its attendant hyperemic condition of the pelvic organs, infection due to gonorrhea contracted before married life begins, and also infections which result from self-inflicted abortions and from unclean puerpera are, in general, the causes and stimuli of the growth of uterine fibroids.

It is recorded by a number of writers, including Kelly of Baltimore and Reed of Cincinnati, and has also been observed by myself, that fibroids may exist in early life and also that they may develop rapidly after the menopause.

The focus points where the fibroma has its beginning are in the uterine glands (Cullen) which project from the mucosa into the endometrium.

The etiology of uterine fibroids is still in dispute, but enough has been discovered which is constant in the pathology of fibroids to grant one the liberty to base an opinion and formulate a treatment which may be curative in a large percentage of cases.

The correct diagnosis is everything in the treatment of any disease, and it is of the greatest importance in helping to guide one in the selection of cases which may be treated successfully locally or which should be turned over to the surgeon for operation.

I am well aware that nearly all gynecologists and surgeons advocate operation, and the removal of all fibroids as an operation is advertised in all cases of appendicitis. Whoever takes this stand that all fibroids must be removed with the knife must remember that a fibroid tumor is not an appendix, neither is the pathology of appendicitis and fibromata the same. One is an active inflammation of the appendix, due to a germ which is virulent in its history and quick in its effects, while the fibroma is due to an irritation of the uterine gland by direct injury or by an infection which causes a chronic irritation, dilating the capillaries and increasing the blood supply, causing a hypernutrition of the uterine glands and fibers of the uterus which ends in an abnormal growth or a fibroid tumor.

The pathology I have hinted at in discussing the cause of fibromyomata. The structure of a uterine fibroid is practically the same as that of the tissues from which it arises; in other words, it contains involuntary, smooth muscle fibers and fibrous connective tissue. Yellow elastic fibers are also found.

There are, at least, three varieties of simple uterine fibroids, the submucous, the interstitial, and the subserous; the names indicate their location.

The symptoms of uterine fibroids can be classified. The very earliest symptom—and I wish to emphasize this one—is painful menstruation from the very beginning. The girl is in pain at the first menstrual period; the mother is called, hot applications are made to the feet and abdomen, and the thing is forgotten until it occurs again. This is the history, which can be elicited in more than 90 per cent. of the patients who have devel-

oped fibroid tumors of the uterus, if the physician is thorough in history taking, and history taking is practised in all cases. This must be practised, for it is the stage in which abnormal growths of the uterus can be prevented, and prevention is of more importance than even a late cure. Pain, bearing down, or a feeling of weight in the back or pelvis, a changed odor to the scanty leucorrhea, blood discharge in the intervals between menstruation; also a profuse flow which is quite noticeable at the regular period. If one gets this history and these symptoms, it will be high time that the woman is examined.

Early Dysmenorrhea.—Of one hundred and ten successive cases of fibromata, in my private practice, the symptom of painful menstruation at the very first menstruation appeared in one hundred and six, and there was only one case which did not give a history of dysmenorrhea at some stage of the growth. The other three who did not give a history of pain at first had pain some time during the development of the tumor. This symptom is of such frequency that it should lead one to suspect a condition of the uterus at puberty which favors a growth during the child-bearing period.

Those girls who have dysmenorrhea at puberty should be supervised and wise treatment should be administered early so as to prevent a fibroid growth. In these cases prevention is more important than the removal of a tumor in middle life.

I am well aware that for me to claim that dysmenorrhea at puberty is associated with a later development of fibroids will oblige me to accept criticism because of my stand. So far as I know, I am entirely alone in these observations. I ask no favor only that, with an unprejudiced mind, you who have the opportunity to make observations will first do so, and then later give your criticism.

Treatment.—There are three methods of treatment of fibroid tumors. First, that of prevention; second, that by medical treatment; and third, removal by the knife.

Preventive treatment of the growth of a fibroid tumor in early life is to remove all sources of irritation of the uterine tissues and this is the first obligation for the gynecologist to assume.

In cases of dysmenorrhea due to atresia of the cervical canal gradual dilatation is helpful. This can be practised without an anesthetic. A thorough disinfection of the uterine cavity with iodine or carbolic acid is of value. Remove ovarian irritation, which causes a hyperemic condition of the uterine tissues, which intensifies all chemical activity of the cell tissues.

If we could hold up all marriages until we are sure that the man had fully recovered from his sexual debauches and, therefore, would not infect his unsuspecting bride, and also discourage abortions, we would have done much toward the prevention of fibroid growths.

A clean, sterile accouchement, with a complete delivery of the placenta and membranes, in all confinements, is another preventive measure.

All measures pursued which successfully ensure complete involution of the uterus are preventive measures which tend to reduce the liability to tumor growths.

Local medical treatment of fibroid tumors. I give you my experience, based upon a series of one hundred and ten cases. Of these cases there were ten which were operated upon, leaving one hundred cases which have been treated locally and systematically. The results are as follows: Of this one hundred there were three who should have undergone an operation but refused.

I now have seven under treatment, six in whom I can see a decided improvement, and the seventh is somewhat benefited, in being relieved of pain and hemorrhage, but is so near the menopause that I hesitate to advise an operation in her case.

Out of the one hundred and ten cases three proved malignant, and were operated on by me; one patient was sixty-four years of age, one thirty-eight, and one thirty-four. All three of these women are living and in fair health.

Four of the one hundred unoperated upon drifted away, but not until they were so much benefited by treatment that they considered themselves well.

Eighty-six cases continued the treatment until discharged as cured. I have watched these women, most of them, and I have failed to learn that any of them has suffered a relapse. The shortest time any of them was treated was three months, the longest time was six years.

Operative treatment. The requirements for an operation depend upon the accuracy of diagnosis.

Only such fibromata should be operated upon as will not yield to anti-inflammatory treatment.

Rules for operating:

1. Submucous and subserous fibromata with a pedicle should, as a rule, be operated upon early.

2. Those tumors in association with which hemorrhage is persistent should be removed.

3. Those tumors that have a malignant tendency should be removed; also those which persist after the menopause.

4. All cases of any variety which do not yield after two months to anti-inflammatory treatment should be removed.

The intramural fibroid almost invariably yields to local and systemic treatment; therefore these should have a thorough trial of such treatment before being given over to surgery.

Fibroid tumors in uteri which are retroverted and held down by the promontory of the sacrum, if released, will, with but little treatment, disappear.

The sexual organs in the female are greatly abused by attempted abortions, methods used to prevent conception, too great requirements by and concessions to the husbands, infections from without, lacerations, and complete retroversions. All these things are insults to the uterine tissues. Because the uterine muscle hypertrophies at times physiologically, under the stimulus of pregnancy, I am led to conclude that any continued stimulus applied may excite a growth in the pelvic organs, which can be cured by treatment and by removing the cause.

I hold that by relieving the uterine tissue of the stimuli which have been mentioned the tumor will disappear by absorption, if taken early. If the tumor is old and the lymphatic terminals and blood-vessels are involved and damaged by blocking, it is more than likely that the tumor is one

that should be removed by the knife. However, these tumors yield to antiphlogistic treatment in a fair percentage of cases.

Conclusions.—1. Dysmenorrhea at puberty is a symptom of a condition which favors the growth of uterine fibromata in later life and should be wisely treated.

2. Prevention of uterine tumors is within the possibilities of the gynecologist.

3. The malignancy in the 110 cases is 2.7 per cent.

4. Operative cases comprised 11.8 per cent.

5. Cases cured by local and systematic treatment were 78.1 per cent.

ACCIDENTS AND COMPLICATIONS OF FISTULA OPERATIONS.

BY CHARLES J. DRUECK, M.D.,

CHICAGO, ILL.

PROFESSOR OF RECTAL DISEASES, HOSPITAL COLLEGE OF MEDICINE,
SURGEON TO FORT DEARBORN HOSPITAL.

Discharge of Intestinal Contents Over the Operative Field.—This is one of the most annoying accidents during a rectal operation. A large sponge should be prepared and passed into the rectum to provide against this, but even with this protection fluid will sometimes be forced through. To prevent this accident the bowels should be thoroughly cleansed the day before operation and an enema given not less than six hours prior to the hour of operation.

When the field has been soiled the operation must be stopped, the sponge plug removed, the rectum irrigated with sterile water or physiological salt solution, a new plug introduced, and the wound thoroughly cleansed.

Hemorrhage.—Hemorrhage during fistula operations need not be serious. If an artery be cut high in the rectum it should be grasped with a hemostat and a ligature thrown around it. If the ligature cannot be fastened a couple of sutures may be passed beneath the vessel and the wound closed. If that cannot be done the hemostat may be left in place for twenty-four to thirty-six hours. Some operators depend upon packing to control bleeding, and if carefully placed this is usually satisfactory. I use very little packing, but prefer the other mentioned methods. Diffuse oozing may be checked with saline compresses held against the surface. All oozing and excessive hemorrhage must be controlled before the dressings are applied and until so controlled the patient must be kept under the anesthetic.

Hemorrhage is particularly liable to follow operations performed under local anesthesia. The first effect of cocaine is to contract the arterioles which lessens the hemorrhage during the operation, but the paralyzing after effect makes secondary hemorrhage a danger, as the parts sometimes bleed excessively. Therefore, it is well for patients who have submitted to operations under cocaine to remain quiet for one or two hours afterward until the after effects of the drug wear off and the parts regain their normal tone.

Styptics, such as alum or perchloride of iron, are undesirable; the clot thus obtained is fragile and

easily displaced at subsequent dressings, and they accomplish nothing but what is better done with compresses or packing.

If ligatures have been applied the subsequent dressings must be carefully handled so as not to slip the ligatures off and cause secondary hemorrhage.

Anesthesia.—It should be remembered during rectal surgery that when the sphincters are stretched deep respirations are excited and the anesthetic mask should be removed at that time or otherwise there is danger of too much of the anesthetic being suddenly inhaled and overcoming the patient.

In nearly all rectal operations temporary retention of urine occurs as a result of the manipulations and trauma which cause edema and congestion of the periurethral tissues. This swelling in turn constricts the urethral lumen. Sometimes retention is caused by spasm of the compressor urethræ and the neck of the bladder. Branches of the long pudendal nerve supply both the sphincter and the compressor muscle. In all operations upon the anterior quadrant of the rectum there is danger of injuring the urethra. As a result of this swelling the urethral lumen is constricted to such an extent that it may be impossible to introduce a soft rubber catheter into the bladder and a silver catheter may be needed. Both types of catheters should be at hand. Repeated efforts should be made by the patient to urinate voluntarily before attempting to catheterize him. Some men patients must get on their feet to urinate. It is well to wait twelve hours after operating before catheterizing unless the patient suffers from distention of the bladder. Do not wait too long, as cystitis and atony of the bladder may follow prolonged retention. Firm packing of the rectal wound may cause retention of urine and may also make the passage of the catheter impossible. In such a case the packing must be removed, when not infrequently the patient can urinate without help. It is well to give urotropin, 60 to 100 grains daily for two days, before all rectal operations because catheterization is likely to cause sepsis.

Involuntary Defecation.—If the colon has not been well emptied before the operation the patient will have an urgent desire to defecate as soon as he recovers from the anesthetic; or the bowels may move involuntarily before he is awake. In such case when the wound has been soiled, the whole anal region and buttocks should be thoroughly cleansed, carefully dried, and fresh dressings applied. When the patient, having recovered consciousness, complains of repeated desire to defecate, he should be permitted to do so, or at least try once. If he has been properly prepared nothing will be voided or at most only a little gas or liquid, and he will be much relieved. If there has been a concealed hemorrhage, which has filled the rectum with blood and is causing the tenesmus, he will void clotted and free blood, and of course require immediate attention.

Shock.—Shock may follow any fistula operation, especially if the patient has suffered a long suppurative siege and also when the cautery has been used. This danger of shock is one of the chief reasons for not using the Paquelin cautery in cases of

extensive fistula. The loss of blood from operations performed with the knife is not nearly so likely to produce shock as is the actual cautery. The loss of blood cannot be replaced with saline rectal injections, but the patient must be given hypodermoclysis or intravenous injections. Otherwise the treatment of shock and hemorrhage following rectal surgery is the same as laid down in all works on general surgery.

Sepsis.—Acute sepsis following rectal operations may develop within a few hours. It seldom comes on later than the third day. It appears usually as a diffuse periproctitis and the possibility of such sepsis renders it imperative that every antiseptic precaution be taken with rectal surgery. Another form of sepsis is that where secondary abscesses develop and in which prompt incision and drainage are indicated.

Incontinence of Feces.—Tuttle says: "This condition has become a nightmare to the profession and a stumbling block to every layman suffering from fistula. It is the shibboleth of the charlatan by which he frightens the sufferer away from the regular surgeon and induces him to be content with palliative treatment rather than submit to an operation." Incontinence does not occur anything like as frequently as is generally supposed. It is quite unusual to have more than temporary incontinence unless extensive burrowings or multiple fistulous openings exist. Incontinence may follow dilatation of the sphincter, but only if there is some underlying spinal or nerve disease, or if the perineum has previously been badly damaged. Oblique, irregular, or jagged incision of the sphincter, even though single, may result in such a vicious union of muscle ends that incontinence results. Transverse cutting of the sphincter is not likely to produce incontinence. The integrity of both sphincters is absolutely necessary for the voluntary control of the anus. If the muscle is cut squarely across and the ends united again so as not to increase materially the muscle length there will be good control. But if a wide band of scar intervenes between the severed sphincter ends the muscle will not contract sufficiently to close the anus completely. Oblique incision of the sphincter allows the divided ends to slide upon one another until the internal fibers of one end unite with only the external fibers of the other end; this very much lengthens the muscle and is frequently followed by incontinence. When the sinus passes through the body of the external sphincter muscle an incision severs only the lower fibers. These may be left to close by granulation. But if the entire muscle is divided and the wound edges retract there is always some incontinence.

Treatment.—When the incontinence is only partial much relief is obtained with galvanic electricity and hot fomentations. These should both be tried before resorting to operative interference.

The operative relief of incontinence depends upon our ability to reunite the severed ends of the sphincter. Our success also depends upon the amount of muscle destroyed in the original operation or the subsequent sloughing of tissues and also upon the length of time elapsed since the damage was sustained. The muscle cut and therefore unused will atrophy and in time is useless if reunited, or it may have degenerated so much that it cannot be

found. If much tissue has been destroyed the muscle fibers may be too short to be brought together. Usually, however, the fibers, because of their imperfect position, are too long to act and the indicated operation by taking out a V-shaped piece shortens and brings the ends into normal position. The mucous membrane is dissected from its base, thus exposing the sphincter fibers and a V-shaped piece, the base outside, the apex pointing in, containing the scar tissue together with only such of the sphincter muscle as cannot be spared is cut out. This cuts the muscle fibers squarely. The ends are now united with chromicized catgut and a tension suture of catgut or silver wire is passed through the skin and muscle one-half to three-fourths of an inch away from the wound. This tension suture should be tied over a pad of gauze and retained for 5 to 7 days. After all oozing is checked the mucous membrane is sutured back into place; none of it is to be destroyed. The patient should be confined to bed, the buttocks being strapped together with a broad band of adhesive plaster to prevent accidental traction on the wound. The patient's bowels are confined for one week and are then emptied with an enema of glycerine 1 ounce and linseed oil 3 ounces. This enema is repeated twice daily until all hard fecal masses in the colon are removed. Then, but not until then, a laxative may be given. The wound must be carefully examined daily to be sure no infection has occurred and no abscess is developing. Should an abscess occur it must be incised early and drained in such a direction if possible that the united ends of the sphincter will not be injured. If the sphincter has been divided in more than one place this operation should be performed in several steps, repairing only one injury at each sitting. The second operation may be attempted a month after the first.

Narrowing of the anal outlet by plastic operation will greatly benefit the patient, but the muscle function cannot be restored. In such a case a buried kangaroo tendon is passed around the anus at the level of the upper border of the external sphincter and tied firmly upon the index finger introduced into the anus.

Prolapse of Hemorrhoids and Mucous Membrane.—Sometimes following a fistula operation, because of the stretching or cutting of the muscle or the tenesmus afterward, there results a prolapse of internal hemorrhoids or of the anal mucous membrane. If this mass falls into the wound it will retard or prevent healing. This procidentia is usually only temporary, and is relieved by astringent ointments and local applications of hot fomentations. If the prolapsing tissue is removed there is danger of its becoming infected if the abscess and fistula are recent. In such a case it had better not be removed unless it is situated just above the angle of the wound, when it necessarily must be excised. In chronic fistula where there is very little suppuration the hemorrhoids may be removed.

Protracted Suppuration and Extensive Burrowing—If, after a careful operation for fistula, suppuration continues it is usually due to some underlying constitutional disturbance, such as syphilis, Bright's disease, diabetes, cardiac disease, or anemia. These conditions should all have been looked

for before an operation was undertaken. Usually where any of them exist no radical operation should be attempted, but our efforts confined to relieving the patient by enlarging the external opening enough to provide free drainage.

If burrowing continues after the fistula operation it is evidence that some small focus has been overlooked or a branch not laid open, or the dressings have been packed too firmly and drainage prevented. When it does occur the burrowings must be promptly and freely laid open their full length. Goodsall says, "The onset of pain in the wound later than eighteen hours following the operation is suggestive of extensive burrowing. This pain is throbbing in character, associated with chill, fever, and swelling near the wound."

If the wound is not carefully dressed each day, the wound edges may unite earlier than the deeper structures and a cavity be left within. This should be prevented rather than cured, but if it occurs the wound must be promptly reopened with a probe or the finger, or if need be incised with the knife. This accident can be prevented at the time of operation by trimming off the skin or mucous membrane edges for one-fourth of an inch on either side of the wound.

30 NORTH MICHIGAN AVENUE.

SOME COSTLY ILLUSIONS IN THE MANAGEMENT OF TUBERCULOSIS PATIENTS.

BY HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

SEVERAL years ago, through the columns of the MEDICAL RECORD, I appealed to our Northern and Eastern colleagues to exercise better judgment than some of them appeared to be doing in the referring of a very large number of hopeless victims of tuberculosis to the far Southwest purely on account of supposed climatic advantages. Somewhat to my surprise, and much to my gratification, I received many testimonials of appreciation concerning that short communication, and I do not desire to appear invidious when I say that the one bearing the autograph of our own illustrious Jacobi was promptly assigned its rightful place at the head of the list.

So far as my observation extends, there has been a notable improvement in the condition mentioned within more recent years, but some illusions die only after terrific struggles and many of them, I fear, are immortal. Some additional words of advice, based upon extended observation, can hardly be amiss at this time. It is unnecessary to add that my remarks are not directed to those who still appear to believe in the miraculous in any branch of medical science.

One day a well-informed layman from the East inquired with some sharpness of tone, "What can be done to stop this procession of walking skeletons from wandering off here to die in misery when they ought to have been kept at home in the first place?"

Some hours later I repeated this inquiry to some colleagues, at the same time expressing some views which appeared to them to be about as heretical concerning the cure of tuberculosis as an edict directed against certain old-time sea practices

might have appeared to the late Captain Kidd. One of them replied: "Why say such things? Why, hundreds of people who were brought here on stretchers are now on their feet attending to business. Just look at our friend Mr. B., who heard an expressman inquire whether to take him to the cemetery or to the morgue!"

As much as I dislike to write a statement apparently so harsh and unfeeling, tuberculosis is a disease only for the rich and the well-to-do. Those possessed of large means may surround themselves with comforts and luxuries wherever they may be located, and so far as this paper is concerned they may be left to shift for themselves. With the poor, there is another story to tell, one neither so short nor so simple as the author of the *Elegy* may have led us to expect.

Only those patients whose danger is detected in the so-called pretuberculous stage should be considered as the ones at all likely to be benefited, and possibly cured, by a radical change of climate. Where the malady has made steady and substantial progress in New York until its real character is at once recognized by street acquaintances and shopkeepers, it may be taken for granted that, while much may be accomplished in the way of prolonging life and palliating suffering, the outcome may be predicted with almost unerring certainty.

All human experience has proved that after the commission of a crime of violence the perpetrator usually seeks safety in flight. A failure to do so generally raises a question involving the mental soundness of the criminal. But the very fact of headlong flight has proved the undoing of thousands of evildoers. The dropping of a key, or a scrap of paper, or a torn garment, may lead to identification and arrest, whereas many a hardened criminal has walked coolly away from the scene of his crime without even a shadow of suspicion following him. In thousands of instances certainly the first impulse of a tuberculous victim when convinced of his danger is to fly somewhere, anywhere, without in many instances taking into the least account the direction of his flight or the safety of his landing place. So anxious is he to leave behind his old surrounding that, as in the case of a criminal, his first step may prove a fatal one. He may leave behind his means of earning a living, his old friends, his family ties, and not infrequently the hard-earned practical wisdom of the old family physician, who may be less familiar with slides and stains than some well-meaning recent graduate, but who does know a great deal about the peculiarities of sick people and the safest and surest means of conserving vital resources and saving life. Tens of thousands of tuberculous victims have lived comparatively long and highly useful lives in New York, Massachusetts, and Pennsylvania who would have died long before from enforced idleness, from lack of proper food, from neglect of skilled medical care, and from sheer homesickness had they flown to some region where they learn too late that climate alone, however salubrious, is only one of the spokes that support the wheel that sustains the weight of the chariot of human life. In general terms, the climate of the far Southwest possesses immeasurable advantages over the inclement regions of the Northwest. The stifling dust storms are far from

pleasant, but they are to be chosen in preference to the nameless spasms of weather that sweep over the greater part of our Northern country. The midday heat for several months of the year in New Mexico is uncomfortable, but is rarely prostrating and never fatal so far as I ever heard. The nights are almost unfailingly cool; in fact, many times too penetrating for pleasant riding, and the tuberculous patient will generally require the same warm garments here that he wears in New York and Boston, gloves and stockings not excepted.

The lover of Nature, and the student of the natural sciences, will find New Mexico abounding in beauties and sublimities of scenery beyond even the imagination to picture. One never wearies of the glowing sunshine and the radiant stars. The rolling, trackless plains themselves are surpassed only by the sky and the ocean.

But tuberculosis, for all its dismal tragedies, pursues its course along practical paths and must be combated with practical resources. The tuberculous subject who sets out for the far Southwest must bear in mind the vital necessity of a sound hull and a steady hand at the wheel. Too often he leaves behind in his old home not only family, friends, the means of earning a living, and the steadfast skill of his medical adviser, but, worse if possible than all these, his last spark of common sense. He has heard much, and perhaps read more, concerning the extraordinary vigor of the typical Southwestern rancher, and immediately makes up his mind that a few months spent in unalloyed sport will lengthen his locks like Samson of old, which it may, and enable him to rebuild the venerable temple, which it will not. That horseback riding is a most wholesome form of exercise for mind and body cannot be doubted, but the primary object of the owner of a stock ranch is to make it pay a return upon his investment. He employs men whose work will insure him a profit, otherwise he would not long remain in active business. Ranch riding, as it is called, is laborious, sometimes very wearisome, and is not free from certain unavoidable risks to life and limb. It cannot in justice be denominated play. Those who engage in it ought to possess elastic muscles, steady nerves, and a reasonable measure of bodily resiliency. The usual food of the ranchers, while abundant and wholesome, is not always prepared and served in such fashion as to appeal to those with sensitive palates, or to those who require a varied dietary.

If not ranching, then some other form of out-of-door work, perhaps. Farm work and crop raising are both profitable and enjoyable under many conditions, but farming is not, and in the nature of things never can be, more than a subsidiary industry in the arid regions of the far Southwest. Some apparently sterile plains and uninviting valleys, when vitalized by abundant water and cultivated with assiduous toil, may yield prolific harvests of the richest products known to the soil; but practical farming as it is conducted under seasonable conditions in the fertile regions of Iowa, northern Illinois, and western New York is unknown here. Aside from the few large mining industries and their allied interests, there is no manufacturing enterprise in the State that would pass for anything important in any large Eastern community.

So far as the odds and ends of labor go, they are generally abundant in every great city, but there is no great city with its vast and complex machinery of manufacture and distribution in this State. All the municipalities in the State, if grouped in one compact area, would not compare in opportunities for labor with any of a hundred that might be named in the old Commonwealths of the East.

As to the patients in whose frames the disease has reached the stormy stage of general infection, those patients whose approach and departure are announced by volleys of explosive coughs, what sensible physician would send them to any far off region with any hope of bettering their deplorable condition? It is even the duty of such physicians to enter a vigorous and determined protest against such pitiable folly. The good people of New Mexico are as full of the spirit of sympathy and helpfulness as the good people elsewhere, but it must be remembered that, however willing they may be, the material resources at their command are not without necessary limitations. Compared with even the least favored sections of Ohio, Indiana and Illinois, New Mexico is a desert, sometimes a desert of surpassing beauty and interest, but yielding little or nothing for the support of man save that which springs from earnest toil and intelligent application of means to ends. There is a ripe field here which some day will be developed by wise and far-sighted philanthropy into some practical form of relief for those suffering from early and curable tuberculosis; but until something based upon scientific lines shall be put upon a practical operating basis, the best possible advice to offer to all who contemplate a change of climate is a modification of a well-known aphorism, amended to read, "Be sure you are right before you go ahead."

RADIUM EMANATION IN HAY-FEVER.

BY FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

MY excuse for reporting these two cases lies in the fact that there is no generally successful treatment known for this trouble, and that the results of the treatment were so prompt and lasting as to warrant a hope that we have at last found a positive method of relief for many of the thousands of annual sufferers from hay-fever.

Of the two cases I have to report, the first patient was treated in the late spring for a general run-down condition, with no thought of its effect on the later affection from which he annually suffered; the other was deliberately treated for the disease in question.

CASE 1.—Business man 30 years old. Had always been well save for an annual severe attack of hay-fever. Was of a nervous temperament. Had been under a prolonged business strain, and came to me for general treatment. This was in May, 1913. He was given a six weeks' treatment with radium emanation and discharged, as far as I could determine in good condition.

I did not see him again until the following winter, when he informed me that he had passed through the preceding summer with no attack of hay-fever. This state of affairs persisted for 3 years, until the summer of 1917, when he came to me suffering from a severe acute attack of the old trouble. On questioning him, I found that for the previous two years he had been

harassed by business troubles, and was in a very nervous and run-down condition. He was started at once on the same treatment as he had previously been given. The relief was prompt, he being able to sleep a good part of the first night, and by the end of the week, there was complete relief of all symptoms. The treatment was continued for two weeks longer, when he was discharged, and had no further trouble during the rest of the season.

CASE 2.—Middle-aged lady, whose previous history showed intense overwork in her younger days, with a condition of semi-invalidism from that time on until within the past 5 years when she has shown a distinct gain. There is a history of severe hay-fever attacks of maximum severity for about 30 years back with no intermission. On figuring up the usual date of the beginning of her attacks I found we had about two weeks' leeway, and I proposed to her that we try and see if we could get any prophylactic result, with a course of radium emanation, the same treatment as I had used in the other case. This was done and the treatment extended over a period of four weeks. As a result she passed through her first summer and autumn with no hay-fever, becoming so bold finally as to weed in her garden and deliberately expose herself to the same influences that formerly had affected her.

To one, like myself, who is daily coming in touch with the marvelous regenerating power of radium emanation over cells, both animal and vegetable, there is nothing unexpected or astonishing in these results. They simply confirm in my mind the belief that I have held that here and there are found individuals whose nerve irritability is far above that of the ordinary and is susceptible to the irritation caused by contact with the pollens and other things that are supposed to cause the disturbance known as hay-fever. Now when these individuals have been treated with the radium emanations a remarkable uplift of nerve strength is developed, and as a result the irritating matter, whatever it may be, no longer causes trouble, for the ever-sensitive nerves have gained the needed tone to resist it.

Whether this is the true explanation or not, it looks as if we had at last got on the track of a rational treatment, perhaps promising permanent relief for the sufferings of hay-fever.

Cervical Phlegmon Due to Vincent's Fusiform Bacillus.—Melchior describes a benign phlegmon due to this organism. There is no mention of any lesion of the mucosa.—*Nederlandsch Tijdschrift voor Geneeskunde*.

The So-called Fifth Cuspid and Hereditary Syphilis.—Mozar and Chenet have thoroughly investigated the claim of Sabouraud that a certain dental anomaly is certain evidence of hereditary syphilis. This anomaly, independently discovered by Sabouraud, had long been known to dentists, but not as an expression of syphilis. Sabouraud then insisted that when his "mamillary eminence on the internal face of the two first upper molars" was present in a certain degree it was specific in nature. The two authors studied the dentition of 60 heredosyphilitic children, with Wassermann control. While 19 who presented the dental anomaly gave a negative Wassermann, they showed the presence of some other affection, chiefly bone, joint or gland tuberculosis. But one child of the 60 showed the fifth cuspid along with Hutchinson's teeth and a strongly positive Wassermann. Thus the association of the anomaly with heredosyphilis is not necessarily one of cause and effect. The children had been treated before the appearance of the teeth and were clinically sound, yet the anomaly developed just the same.—*La Presse Médicale*.

Military Medicine.

TESTS FOR THE PERCEPTION EFFICIENCY OF RECRUITS.

BY ALLAN McLANE HAMILTON, M.D., LL.D., F.R.S.E.,
GREAT BARRINGTON, MASS.

IT is to be regretted that more explicit directions for the investigation of the mental condition of the recruit are not available, but the physician is simply told in the Selective Service Regulations of the United States that he must conduct such an examination "as to develop, whether or not the man examined is possessed of sound understanding," and obtain a history whether he has had epilepsy or previous mental disease. The first demand has its difficulties, for under ordinary circumstances it is a matter of some difficulty even for a trained observer when ample time is afforded to do this, which is not the case in the selection of recruits.

While modern psychology and psychiatry have made such strides as to render the task easier than when the Service Regulations were devised, there is a temptation to resort to ready-made tests of a general character and an arbitrary system of mensuration which has not only been utilized heretofore to gauge the intelligence of children, but is now used in many parts of the country to ascertain the intellectual fitness of soldiers. So far, it has been found unsatisfactory, consuming time and revealing little. The best known test is the so-called Binet-Simon, which seeks to fix positively the degree of intellectual development of the young at various ages, but does not indicate emotional changes or many other things that are necessary to be known, among them the existence of physiological and affective idiosyncrasies.

Haberman¹ in an excellent article suggests tests that are a great improvement upon those just mentioned, and says in speaking of the Binet-Simon method: "The examination and evaluation of a child's intelligence is a most difficult procedure. No method of absolute computation of the normal general mental ability exists, not even a relative computation, and, at best, our conclusions are based on single facts which we ascertain. In other words, we estimate the whole by gauging a separate part, or better still several separate parts." The Binet test, as we know, arbitrarily fixes the degree of intelligence at certain ages, ignoring all the influence upon the individual of environment, education, nationality, example and other things; for this reason it is impracticable and unreliable. Haberman refers to Meumann, who is equally opposed to the test just mentioned. "He also states that the questions are not tests of intelligence, but of quite various things, some being purely psychologic (of psychologic functions), some of knowledge, the latter again partly such as the child learns from those around him (picked up at home or on the street or at school), partly gains through his own observations. All the latter do not test his ability as such, but only the influences of 'milieu' on his ability, etc. These are tests of functions and knowledge mixed (as the language tests, etc.)."

A more satisfactory and exact method consists of the Yerkes-Bridge² Point Scale test, the basis, however, still being the Binet-Simon suggestions

from which it seems difficult to escape. Here the ability to answer the questions—*independent of age*—determines the extent of intelligence, and the degree of correct responsiveness indicates the intellectual soundness and development.

When the observer examines the tasks imposed upon the subject by the various tests provided by many inventors of schemes, and he need not be hypercritical, the impression is immediately created that the requirements of a normal standard of intelligence consist in a collection of necessary attributes which are more or less trivial and fanciful. These certainly are of questionable value when we come to apply them to determine the intellectual fitness of the *adult* recruit. There is something amateurish in the selection of silly anecdotes and catch questions, which are supposed to require answers or explanations indicative of the degree of critical moral and ethical sense of the soldier! They are, besides being impractical, great consumers of time. Dr. R. Sheehan³ of the Navy says: "Are we justified in taking twenty-five minutes of the medical officer's time to use a measure that detects only a small part of the undesirables?" The present efforts to apply psychological tests, therefore do not seem to possess the merits of simplicity, nor are they adapted to the recruit.

We are told that various committees from the American Psychological Society, none of whom are psychiatrists, are covering the country applying tests to officers and men which are obviously insufficient, because laboratory methods are relied upon. Again we find the painstaking subordinates of the Surgeon-General's office devoting their time to the estimation of the mental fitness of the recruit without regard to the needed psychic requirements of the soldier, such as his ability to remember rows of figures after hearing them read or seeing them, or by making him reconstruct and re-assemble the parts of dislocated tools or mouse-traps, etc.

They, however, are moving in the right direction by examining recruits in groups of two hundred or more, although it seems as if the tests should be directed to the evident need of finding out *what special mental equipment the fighting man needs*, and whether he falls short or not. If time is an object there is no economy in examining him as one would a school child or a person in civil life.

1. It would appear to most people that a competent soldier should possess (besides a sound body) sufficient knowledge of the English language to understand and obey orders. To determine this he should among other things be given tasks to perform by written and oral command. Great care, however, should be used in excluding ignorant men, for many of the hardy mountaineers of Tennessee, Kentucky, North Carolina, and western Virginia, as well as other regions, neither read nor write, but make excellent soldiers and are noted as marksmen.

2. Quickness and the extent of *comprehensive vision* is a necessary attribute for a capable soldier. This consists in the individual's capacity to form rapidly, concepts of as large a number of objects as possible in a given area, and after visualizing them, record them immediately. (This may be done with groups of men by means of the magic lantern, proper slides, preferably in monochrome, being used

which portray landscapes and figures, or colored objects by which the color sense may incidentally be tested. The pictures should be exposed for from 3 to 5 seconds, according to the complexity of the subject, and the recruit is briefly to record upon a pad his impressions of the details.)

3. The detection of sounds and flashes of light; time of threshold perception, and nature of the resulting concept; direction, nature, and intensity, quality, *e.g.* from right or left side, behind or in front? loud or faint? intense or dim? "roaring," "ringing," "whistling?" Suitable instruments should be used for these tests that may suggest themselves.

4. The estimation of alertness, muscular co-ordination, stereognostic sense, balancing, and steadiness. (The writer has utilized the small Japanese "maze" puzzle by which small balls may be directed through sinuous tracks and concentrated into a small central receptacle. This operation should be accomplished in less than five minutes.)

For the more extended test of officers or doubtful cases it is, of course, necessary to avail ourselves of other measures, and the advanced Habermann tests, or the Yerkes-Bridges Point scale are available.

As considerable fault has already been found with the alleged unnecessary use of all psychological tests at this time, there is a demand for simplicity which cannot be disregarded. "The charge is being made that we are pursuing such refinements in our selection of men to fight battles," writes a friend who occupies a high position in our national affairs, "as to be embarrassingly obstructive to producing expeditiously the men required. We are apt to think that we have got plenty of time to pursue refinements. So far as I know these tests have never been applied in time of peace, when there was ample time to indulge in refinements."

Although, so far, from 2 to 5 per cent. of recruits have been rejected for nervous and mental disqualifying conditions, it seems as if we should not be too exacting in our selection of soldiers so far as tests of mere intelligence are concerned. The native-born fighting man of America has time and time again proved his intelligent worth even after a preliminary period of confusion and perhaps disorder, and even when he has not had the continued intensive training which is a feature of other armies.

General Crozier,⁴ who was attached to the Pekin relief expedition, had ample time to observe the behavior of the American soldier at a time when no intelligence tests were in use. After commenting upon certain shortcomings of the men who were slouchy and untidy, and "failed to salute their officers," and often acted on their own responsibility, he said: "It is not intended to convey the impression that the Americans constituted anything like a mob; their control was never in the least degree out of hand, and they showed themselves, as heretofore, perfectly amenable to such discipline as was exacted. *They were the most intelligent of all the troops forming the expedition*, as was strictly apparent from observation of their faces at the good opportunity afforded by the march past the staff at the entry of the Forbidden City, on which occasion also their neatness and fine appearance was most gratifying." Upon this occasion they were seen in

comparison with the English, French, Russian, Japanese, and German troops, so the test must have been a highly satisfactory one.

THE SOLDIER CAFARD.

THE word "cafard" is rendered in English by "canti-humbug" or "hypocrite," although we would not refer to a splenetic neurasthenic as a hypocrite. Nor do the French, in applying the word cafard to certain soldiers, confound them with malingerers. A new meaning of an old word has come into use during the present war, which refers purely to a state of mind, a peculiar depression, a morbid condition of the psyche, inconceivable in former times, as a result of life at the front. The odd thing about this word cafard is that it is used in self-reproach and not as an epithet of derision or reproach to others.

In the *Journal de Médecine de Bordeaux* for December 25, Caussimon describes the "cafard" feeling, which he has often experienced. A soldier whose appearance is rational throughout, and who is in the midst of his regular duties, suddenly experiences a feeling of repugnance or unsurmountable fatigue. Nothing more burdensome can be conceived. In its mildest expression it can be thrown off with an effort of will, but as a rule the condition is cumulative. It seizes its victim not only when he is idle, but when he is in the midst of execution of well-laid plans. In certain cases there is a sort of prodromal state. He feels out of sorts and slows up in his work. Generally speaking, the condition is unforeseen and unmotivated. At times one has a presentiment on waking that a bad day is before him, and will say, "I feel the cafard coming," and make no attempt to fight it. In the midst of the crisis he retains, so to speak, only a fourth of his value as a soldier. He is now transformed, wholly indifferent to his surroundings. He scowls, with drawn features, and his appearance suggests both powerlessness and extreme suffering. Every movement is an effort, and, moreover, attended with pain. He immobilizes himself, or else wanders about aimlessly, and can no longer think; becomes almost mute, and reacts to no form of irritation. The picture in no wise recalls the condition of extreme asthenia at the front, as described by Cheyron (*MEDICAL RECORD*, February 2, page 195), in which there are marked lumbago and fever. The "cafard" does not care to eat, although he feels the pangs of emptiness. Mostly he keeps his bed, although when the attack is mild he may endeavor to keep going. He loses all his inculcated respect for cleanliness and spruceness; in fact, his slovenliness is characteristic. The cafard becomes not only very anxious about his future, but seeks a motivation for his condition, and in his weakened mental state may develop a fixed idea. His condition is certainly not simple neurasthenia, nor is it psychasthenia,

although the latter resembles it in many ways. The psychasthenic often suffers by crises like the cafard, but the latter never complains of headache or neuralgia. This is the more remarkable because the mental state of the cafard comes nearer that of migraine than of any other neurosis. True melancholia can be excluded, although "melancholy" is the nearest popular term suggested by the cafard soldier.

Eye Changes in Trench Nephritis.—During the spring of 1917 J. Kirk, Late Temporary Captain, R. A. M. C., and specialist in ophthalmology, had the opportunity while on duty at Malta of examining a series of cases of trench nephritis, or war nephritis. There were about eighty cases and they all came in the same convoy from the Macedonian front. They were chiefly young soldiers between twenty and thirty, although there were a few older men among them. The history was generally the usual one of fairly severe exposure and strain, though not necessarily in the front line. The majority of the cases presented the disease in a severely acute form and on admission were seriously ill. At that time the fundi of a large number were examined and almost invariably retinal congestion with large pulsating veins were found. There were no signs then of any patches of exudation or nerve involvement. Some weeks later, however, there were found in one or two patients, who complained of eye symptoms, more definite changes of nerve swelling, accompanied by patches of retinal exudation. The whole series were then again examined and the following results found. For convenience they were divided into three groups.

Group A numbered about 21. They were all convalescent, presenting practically no symptoms except slight anemia and debility. The urine was free from albumin, except for a very slight trace in a few. In only four of this class were retinal changes found, and they were slight in amount—a few small spots of exudation, a small punctate hemorrhage, a slight haziness of the disc edges, or a little edema along the course of the veins.

Group B—a series of 20 cases who had not done so well as the others. Albumin was generally present, though in small quantity. There was breathlessness and slight edema often. Of these cases, 8 showed minor retinal changes, with small exudation spots. One, however, showed much more marked changes, pointing to a fairly severe neuroretinitis.

Group C, 13 in number, were severe cases in which the disease was still marked. They were suffering from general symptoms, severe edema with often a large quantity of albumin in the urine and sometimes blood. Of these 13, 4 showed very definite retinal changes and 4 changes of a slighter nature.

So far as could be ascertained, there were no signs of any other complicating disease, with the exception that several cases showed malarial infection. In none was there any history of previous kidney attacks. In 9 of the cases presenting the more severe retinal changes a Wassermann test was done, and in all of the 9 the result was negative.

Some points in regard to the fundus changes are: (1) That while the spots of exudation were generally in the usual situations—that is, near the disc and in the macular area—in no case was seen the typical silvery star-like figure of the chronic cases as figured in the textbooks. (2) Hemorrhage was not common. Those seen were of the small punctate variety, and not of the striate or flame-like character. (3) The optic disc was often affected, the changes varying from a definite swelling to slight woolliness and indistinct edges. (4) Small areas of edema were noticed, especially along the course of the veins. (5) An important point was that in several of the series there could be traced the gradual absorption of some of the smaller patches of exudation, and the healing process was very interesting to watch.

Kirk, in a summation of his results, gives the following conclusions: (1) That in this disease the retina is very liable to be involved, although gross changes are not evident in the early stages, and latterly changes which had been present may have become absorbed. (2) That the pathology is probably an acute congestion resulting from some specific toxin, that the exudation which ensues is partly lymphoid and partly cellular in nature, and that this deposit probably clears up in the great majority of cases, without leaving any permanent results. (3) That the retinal changes do not affect the prognosis, except in so far that the severer these changes the severer the cases, in many instances, though by no means necessarily so. (4) That the condition is one which is probably allied to the acute retinitis of pregnancy, scarlatina, and acute uremia, and should not be confounded with the retinitis of chronic kidney inflammation with its permanent changes in the retinal circulation vessels and tissues.

The Treatment of Flat Foot.—The *Monthly Bulletin* of the New York State Health Department publishes the experience of Major Isaac W. Brewer, in a series of about 400 men from various parts of the country who were placed under treatment by Lieut. H. B. Perry, M. R. C., at Fort Ethan Allen, Vermont, about 90 per cent. of whom were returned to the ranks cured.

Of the white men who applied for enlistment in the United States army during the period from 1912 to 1915 inclusive, 55 out of every 1,000 were disqualified because of flat foot. Thirteen per cent. of the men examined since the outbreak of war were rejected for this reason. A much larger number of men had flat feet, for those with this deformity in moderate degree were passed. A large number of the men who were so passed later appeared on the sick list, because the condition of their feet precluded their engaging in the strenuous exercise incident to the training of the soldier. The following exercises for the treatment of flat foot are those that have been found adapted to conditions met with at an army post and now in practice at Fort Ethan Allen, Vermont. The feet and legs should be free. Shoes and stockings should be removed. Underdrawers and breeches loosened so as in no way to restrict or limit muscular action of the legs. The toe exercises are the first ones taken up. The men stand on a raised platform—a 2-in.

plank is sufficient; they are then directed to flex the toes to the extreme point of flexion with a hard pull of the flexor muscles of the sole of the foot at the extreme point of flexion. This is followed by extension without effort. This exercise is repeated continuously from five to ten minutes, the shorter period at the beginning, gradually lengthening the time of this particular exercise until the full time is possible without fatigue. The second exercise is a continuation of this flexion of the toes on the sole of the foot, plus inversion of the foot to the extreme, bringing into the action the *tibialis anticus* muscle. At the extreme point of inversion a *strong, hard pull is made*, then the foot is allowed to resume its usual position without any muscular effort.

At the beginning, fifteen or twenty minutes is sufficient for the entire routine of exercise. Later, after the muscles become stronger, a full half hour may be devoted to this without marked fatigue. The plan as outlined above should be carried out each morning under the supervision of a man trained along this line. The patients should be instructed to repeat this performance each night on retiring, devoting one-half the time consumed in the morning. Many of the cases with marked eversion of the foot walk with the toes turned out. The men are instructed to walk with the toes turned in at all exercises and at all other times during the day. We believe that this latter advice relative to walking is vitally important in the general handling and treatment of these cases.

Artificial Limbs for Disabled Soldiers.—The application of artificial limbs in Australia is described in a pamphlet by Sir Thomas Anderson Stuart, M.D., Dean of the Faculty of Medicine of the University of Sydney. The writer has found great difficulty in getting disabled men to realize how much can be done to improve their lot. They tend to become discouraged with the irksomeness and discomfort of the unaccustomed burden of an artificial limb. Great temporary weakness and lassitude of the remaining tissues, which are just those to which the artificial limb is attached, follow severe amputations as a matter of course. These become permanent in the case of healthy parts, however, only if left unexercised. The utilization of the stump in doing actual work, through the instrumentality of a light, inconspicuous, and suitably constructed artificial limb, gradually restores both strength and vitality. The temptation which the patient at first finds almost irresistible to unburden himself of the unaccustomed appendage soon gives place to pleasurable interest and pride in finding himself enabled to resume profitable occupations from which he had believed himself forever debarred. The artificial limb, as is pointed out, should be such that the patient likes to wear it. When the limb really fits him, the physical and mental comfort which it brings to the wearer is beyond expression; it converts the desponding into hopeful, active, useful men. The Germans are supplying two limbs, one strong and simple, provided with hook or ring, or other device, for the man's everyday work, and a Sunday arm for walking out. To most patients the main thing is that the limb should be of practical use in their work, but the limb and its movements should be natural looking, for that will help the wearer to get employment.—*Recalled to Life*, No. 2.
